Ellenberg & Rifkin's

DIABETES MELLITUS

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

ISBN: 0-8385-2178-9

This book was set in Times Roman by The Clarinda Company.
The editors were James Shanahan, Susan Noujaim, and Barbara Holton.
The production supervisor was Richard Ruzycka.
The index was prepared by Katherine Pitcoff.
Quebecor World Kingsport was the printer and binder.

This book is printed on acid-free paper.

Cataloging-in-Publication Data is on file for this book at the Library of Congress.

PREFACE

This new edition reflects the many changes and rapid developments in the field of diabetes mellitus. The sixth edition adds a new editor as well as new authors and topics, but maintains our focus by asking the authors to present those areas of the greatest significance and general use to the field. We believe that we have produced a book which covers the complete spectrum of what has become an increasingly important medical epidemic affecting more than 135 million patients around the world. The scientific basis for the disease remains the focus of the first half of the book and reflects the rapid increase in scientific developments in our understanding of carbohydrate and lipid metabolism. Here the impact of these exciting and novel biological insights, which are so important to clinical pathophysiology and treatment, is heavily emphasized. This is most readily seen in the completely revised chapters on the molecular and cellular biology of the β -cell, the mechanisms of insulin action, and the biochemical mechanisms of microvascular disease. The impact of the revolution in the molecular understanding of disease is also evident in many other contributions such as the new chapter on vascular thrombosis and endothelial dysfunction, the molecular mechanisms and genetic engineering of insulin secreting cells, and the chapters on the pathophysiology and genetics of type 2 diabetes, the immunology relevant to diabetes, and the pathophysiology and genetics of type 1 diabetes. Change is also reflected by our adding six entirely new chapters and 22 new authors. Thus the book continues to evolve at the same rapid rate as the field.

In the pathophysiology area there has been extensive revision of our view of integrated metabolism and major updates on the mechanism involved in the complications of the disease plus several new chapters on the specific mechanisms for the eye, kidney, and nerve complications of the disease. The impact of the explosion of understanding of how body weight and adiposity are regulated is presented from both a basic perspective of the process to the clinical significance of the interaction between obesity and type-2 diabetes. Reflecting the final agreement between European and American organizations including the American Diabetes Association, National Institute of Health, and World Health Organization, the terminology type 1 and 2 diabetes is used throughout the text and the updated standards for the diagnosis and classification of these forms of diabetes are presented in the new chapter on this topic.

Clinical aspects of diagnosis, treatment and management are the focus of the other half of the book which also contains a number of new chapters and authors. The major recognition of the importance of good plasma glucose control to diabetes complications

is strongly represented for both type 1 and 2 diabetes and new treatment modalities and pharmaceutical agents for both forms of the disease are presented and their use discussed. Chapters on patients with complications also focus on specific diagnostic tools and their use for the prevention and management of each complication including discussion of the newer methods and treatments which most critically address these associated disorders. Reflecting the increasing recognition of cardiovascular disease to the shortened life expectancy of this patient population there are several new chapters on the mechanisms of macrovascular disease and the impact of all of the major risk factors on its clinical manifestation including hypertension, dyslipidemia and endothelial and hematological dysfunction. In each of these areas potential treatments are reviewed and compared, and where possible, related to mechanisms and outcomes. Finally, there are chapters on the behavioral, economic and educational factors that are so important to patient well being and comfort. In addition we look to the future with a chapter on new treatments on the horizon that are playing such an important role in the rate of change of everyday clinical practice and that reflect the enormous interest of the biotechnical and pharmaceutical industry in the field. Thus clinicians will find the biochemical and physiological basis of disease available to them as new treatments are developed that are based on this fundamental understanding of disease. At the same time scientists who wish to develop these new treatments will have the missing elements of present day treatment approaches clearly enunciated in the clinical sections of the book to assist them in understanding how the biochemical and physiological mechanisms express themselves clinically at the present time. We hope this book will prove useful to all those interested in any and all aspects of this protean medical problem.

As is always true, we are indebted to our authors for their untiring effort to provide the most complete, most efficient information in their chapters and their forbearance with the comments of their editors during this process. We also wish to recognize the loss of our dear friend and founding editor, Harold Rifkin, whose philosophy to do what we can to help patients remains our guiding light. We also wish to acknowledge and thank the staff of our new publisher, McGraw-Hill, for their help and support in bringing this book to you and express our immense appreciation to the loyal and dedicated assistants at our institutions, Tessa Trowbridge, Bethan Heintz and Kathleen Catalano who were critical to all of the administrative details that are so necessary, allowing the editors to focus on the intellectual challenge of this project.

*The editors dedicate this book to Eunice
Porte, Leslie Sherwin, Marilyn Baron, and
Bibi Rifkin for their loving patience,
understanding, and support.*

DIABETES MELLITUS

Integrated Fuel Metabolism

Gerald I. Shulman

Eugene J. Barrett

Robert S. Sherwin

INTRODUCTION

Regulation of fuel metabolism in humans involves a complex interplay between hormones, exogenous nutrients, and interorgan exchanges of substrates designed to maintain a constant and adequate supply of fuel for all organs of the body. The key regulatory hormone orchestrating the exchange and distribution of substrate between tissues under fed and fasting conditions is insulin (see Chaps. 3 through 5). Glucagon, catecholamines, cortisol, and growth hormone play major roles in energy regulation during times of acute glucose requirements, such as during exercise, under stress, or in response to hypoglycemia (see Chaps. 9, 27, and 31). The major organs involved in maintaining fuel homeostasis are the liver and kidney, by virtue of their unique ability to produce glucose; the brain, due to its almost total dependence on glucose as an energy source; and the muscle and adipose tissue, due to their ability to respond to insulin and store energy in the form of glycogen and fat, respectively.

The purpose of this introductory chapter is to review how humans utilize energy and the means by which the body manages its energy stores during times of feeding, fasting, and exercise. In addition, a brief overview of the impact of diabetes on these processes is presented.

FORMS OF ENERGY

Ultimately, all animals sustain life from the energy released by the breaking of carbon-carbon bonds formed in plants during photosynthesis. Cellulose is the principal form of this stored energy in the biosphere. It consists of polymers of glucose joined by β 1,4 linkages. In contrast to the α 1,4 linkages that occur between glucose molecules in glycogen and other edible starches, cellulose is not digestible by humans. However, most ruminants harbor cellulase-producing bacteria in their digestive tracts which can degrade cellulose to glucose and therefore take advantage of this abundant energy supply. Energy in foodstuffs exists in three forms: (1) carbohydrate, (2) protein, and (3) fat, which in turn consist of three basic units: sugars, amino acids, and free fatty acids. It is self-evident, glycogen is the main storage form for carbohydrate in humans. It is a macromolecule (10^6 – 10^8 kd) consisting of branching chains of glucose bonded by α 1,4 or α 1,6 linkages. It is stored by

most cells, with the highest concentrations occurring in liver and muscle. Glycogen is highly hydrophilic, with 1–2 grams of water stored with each gram of glycogen. Storage of energy in the form of glycogen is therefore relatively inefficient on a weight basis, yielding not the theoretical 4 cal/g of dry carbohydrate but rather only 1–2 calories for each gram of hydrated glycogen. Unlike carbohydrate, protein is not accumulated in humans as a primary energy reserve. Instead, each molecule of protein serves other important biological functions. In the healthy adult human eating a weight-maintaining diet, amino acids derived from ingested protein replenish those proteins that have been oxidized in normal daily protein turnover. Once these protein requirements have been met, any excess protein is either oxidized to carbon dioxide or, if there is energy excess, this excess protein is ultimately converted to glycogen or triglyceride. Like glycogen, most proteins are significantly hydrated and therefore the energy stored per gram of protein is less than the 4 cal/g of dry protein. In contrast to glycogen and protein, fat is stored in a nonaqueous environment and therefore yields an energy level very close to its theoretical 9.4 cal/g of triglyceride. This greater efficiency of energy storage provided by fat is crucial for all animals in that it allows for greater mobility and prolongs survival during famine.

FUEL STORAGE

A healthy adult human uses approximately 1 cal/min or 1500–1800 cal/d to meet basal energy requirements.¹ Energy expenditure may increase as much as two- to threefold with exposure to a cold environment or during the performance of heavy exercise.² Table 1 provides an estimate of the amount of energy stored in glycogen, protein, and fat in a normally proportioned 70-kg human. As can be seen, if glycogen were the sole source of calories, liver and muscle stores would be rapidly depleted, furnishing calories for less than 1 day's resting energy expenditure. Body protein mass is much larger with nearly half contained within skeletal muscle (~6 kg). This potentially could provide ~10–15 days' worth of energy. However, energy stored as protein serves important enzymatic, structural, regulatory, and locomotive functions, which if compromised would be very detrimental to survival. On the other hand, whole-body triglyceride stores (mostly in adipose tissue) are normally sufficiently large to provide fuel for several months.

TABLE 1-1. Approximate Distribution of Body Fuels and Their Potential Energy in a 70-kg Adult Human

	Kilograms	Kilocalories
Adipose tissue triglyceride	12	108,000
Muscle protein (dry weight)	6	24,000
Carbohydrate (dry weight)		
Muscle glycogen	0.3	1200
Liver glycogen	0.1	400

survival depending on the level of physical activity. Therefore, while humans have two large storage depots of potential energy (protein and fat), fat serves as the major expendable fuel source. Thus, when less energy is taken in than is required to meet metabolic demands, the body initially draws on its limited quantities of hepatic glycogen, but soon adapts so it can draw on its fat reserves to meet energy demands, thereby minimizing its loss of body protein stores. Similarly, when more energy is ingested than is being oxidized, excess calories are stored as glycogen and/or fat. There also exists a hierarchy for energy interconversion that is unidirectional in that amino acids can be converted to glucose and fat, and glucose can be converted to fat; however fat, once formed, can only be stored or oxidized.

FUEL UTILIZATION

There are three main priorities that humans have for fuel utilization. The first priority is accorded to maintaining a stable supply of substrate for central nervous system function. The brain has little stored energy in glycogen or triglyceride and therefore depends on the liver (and under some circumstances the kidney) for a constant supply of energy. In the fed state and early in fasting the brain derives essentially all of its energy for function from glucose oxidation. Most other major organs of the body (muscle, liver, and heart) fill their energy needs at this time by oxidizing fatty acids. However, the blood-brain barrier is impermeable to fatty acids, restricting their use by the brain.³ As a continuous supply of glucose is required to meet the energy demands of the nervous system, humans have evolved elaborate, redundant mechanisms to maintain plasma glucose concentrations within a narrow range between 55 and 140 mg/dL under both fed and fasted conditions. Lower glucose concentrations impair brain function, whereas high glucose concentrations exceed the renal glucose reabsorption threshold, resulting in wasting of this valuable energy source. In contrast, fatty acids and the water-soluble by-products of incomplete fatty acid oxidation, β -hydroxybutyrate and acetoacetate, can vary in concentration by 10- and 100-fold, respectively, depending on the fed/fasted conditions.⁴ During prolonged fasting (>2 days) plasma β -hydroxybutyrate and acetoacetate concentrations rise sufficiently to supply much of the brain's oxidative fuel needs.⁵ Thus the brain indirectly uses fatty acids as an energy source.

The second priority for the body is to maintain its protein reserves (i.e., contractile proteins, enzymes, nervous tissue, etc.) in times of fasting and replenish them during feeding. This has obvious survival benefits.⁶

The final priority is to replenish its limited liver and muscle glycogen reserves following a meal. Once these stores are full, any excess energy in the form of carbohydrate and protein is converted

to fat. Muscle glycogen is the most readily available form of energy for muscle contraction, especially when intense bursts of physical activity are required, and therefore maintaining an adequate supply of muscle glycogen at all times also has obvious survival benefits in times of fight or flight.⁷

METABOLISM DURING FEEDING

Three mechanisms exist to maintain normoglycemia following carbohydrate ingestion.⁸ They are: (1) suppression of hepatic glucose production, (2) stimulation of hepatic glucose uptake, and (3) stimulation of glucose uptake by peripheral tissues, predominantly muscle (Fig. 1-1). Insulin is the primary signal that orchestrates the storage and metabolism of glucose.⁹ While glucose is the dominant mediator of insulin secretion, stimulation of insulin secretion with meals involves coordination of multiple effectors (see Chap. 4). This becomes apparent when comparing the insulin response between identical amounts of glucose given intravenously versus orally.¹⁰ Oral glucose raises insulin severalfold higher than comparable glycemia achieved by giving intravenous glucose. This differential insulin response is due to the secretion of multiple incretins from the pancreas and gastrointestinal tract [of which gastrointestinal peptide (GIP) and glucagon-like peptide (GLP-1) appear to be most important], as well as to signals from the central nervous system (parasympathetic innervation of the β cells of the pancreas) in response to local GI stimulation.¹¹ The incretins and neural signals prime the β cells so as to increase the release of insulin following meal-induced increases in blood glucose. This "priming" of insulin release is absent when blood glucose increases as a result of increased hepatic glycogenolysis in response to stress, thereby avoiding potentially detrimental hyperinsulinemia under these conditions.

The rise in portal vein insulin and glucose concentrations in conjunction with a reduction in portal vein glucagon concentration following a carbohydrate-containing meal suppresses hepatic glucose production and net hepatic glucose uptake ensues.¹² In this manner the liver buffers the entry of glucose from the portal vein into the systemic circulation and minimizes plasma glucose excursions, while at the same time promoting glucose storage. Once the meal is absorbed and blood glucose returns to baseline, the liver resumes net glucose production to maintain normoglycemia. Depending on the size of the carbohydrate load, anything from a quarter to a third of the ingested exogenous glucose load is taken up by the liver.¹²⁻¹⁴ It should be emphasized that since the liver is not only decreasing its production of glucose, but also taking up a significant amount of glucose, the contribution of the liver to postprandial glucose homeostasis is substantial and approaches that of muscle. Glucose taken up by the liver during the meal is predominantly stored as glycogen.¹⁵ Using ¹³C NMR spectroscopy to non-invasively monitor hepatic glycogen content in humans, recent studies have demonstrated that hepatic glycogen stores peak 4-6 hours following a meal.¹⁶ As a result, when meals are ingested at 4- to 6-hour intervals (e.g., breakfast, lunch, and dinner), hepatic glycogen increases throughout the day in a stepwise fashion while most of the glucose required for metabolism is derived from exogenous glucose absorption¹⁷ (Fig. 1-2). Having reached its peak at around midnight, hepatic glycogenolysis supplies glucose for the brain and other glucose-requiring tissues during sleep.

Recent studies have demonstrated that liver glycogen is synthesized by both a direct (glucose $\rightarrow$ glucose-6-phosphate $\rightarrow$ glucose-

FIGURE 1-1. Whole body fuel metabolism in the fed state following a carbohydrate meal.

1-phosphate $\rightarrow$ UDP-glucose $\rightarrow$ glycogen) and an indirect [three-carbon units (lactate, alanine, glycerol, pyruvate) $\rightarrow$ glucose-6-phosphate $\rightarrow$ glucose-1-phosphate $\rightarrow$ UDP-glucose $\rightarrow$ glycogen] gluconeogenic pathway.¹⁸⁻²⁰ When a meal is ingested following an overnight fast, these pathways contribute roughly equally to hepatic glycogen synthesis. However, the relative contribution of these pathways appears to depend on many factors, including the composition of diet, the level of glycemia achieved during the meal, and the relative concentrations of insulin and glucagon. Specifically, a high-carbohydrate diet, hyperglycemia, and insulin promote the direct pathway,²¹ whereas reduced carbohydrate intake, lower glucose levels, and elevations in circulating glucagon stimulate the indirect pathway.^{22,23} One of the recent controversies regarding hepatic glycogen synthesis has been the source of the three carbon units that are used for the indirect pathway of hepatic glycogen synthesis. While muscle, skin, and erythrocytes are all potentially important sources of lactate and alanine for the indirect pathway of hepatic glycogen synthesis, recent studies in dogs and humans have demonstrated that following a glucose meal the liver takes up enough glucose to account for all of the glycogen synthesized by both the direct and indirect pathways.^{22,23} These observations might be explained by either hepatocyte heterogeneity in that periportal cells may be predominantly gluconeogenic and perivenous hepatocytes may be predominantly glycolytic, or by substrate cycling between glycolysis and gluconeogenesis within all hepatocytes. Recent studies in rats, in which the relative fluxes for glycogen synthesis in periportal and perivenous hepatocytes have been examined, are consistent with the latter mechanism.^{24,25}

Glucose escaping the splanchnic (liver and gut) circulation is cleared predominantly by muscle where most is stored as glycogen.^{12,26} The remaining glucose is metabolized via the glycolytic pathway and then is either oxidized or recycled back to the liver as three-carbon intermediates. The uptake of glucose into muscle as well as adipose tissue is predominantly mediated by a rise in in-

sulin concentration and to a lesser extent by the mass effect of hyperglycemia *per se*. Insulin promotes translocation of the GLUT transporter to the plasma membrane and thereby stimulates glucose uptake by muscle and fat.^{27,28} In addition, insulin modulates subsequent metabolism of glucose by increasing the activity of glycogen synthase,²⁹ thereby promoting glucose storage, and increasing the activity of pyruvate dehydrogenase,³⁰ thereby increasing glucose oxidation as well.

While adipose tissue typically represents a large component of the peripheral mass (~12 kg), glucose utilization by adipocytes in humans represents a relatively small sink for ingested glucose. There is relatively little *de novo* free fatty acid synthesis from glucose in human adipocytes, likely due to the relative lack of citrate lyase.³¹ The glucose that is metabolized by adipocytes does, however, serve an important role for triglyceride synthesis in that it is used to generate α -glycerol phosphate, which is required for triglyceride synthesis. In times of caloric and carbohydrate excess, the liver (which has abundant amounts of citrate lyase) synthesizes fatty acids *de novo* from glucose, esterifies the fatty acids to triglyceride, and exports them to the periphery in the form of very low density lipoprotein (VLDL) particles (Fig. 1-3). The triglyceride in VLDL is hydrolyzed by endothelial lipoprotein lipase to release fatty acids. Subsequently, the fatty acids are reesterified and stored as triglyceride in the myocyte and adipocyte.

The larger the meal, the greater is the rate of glucose uptake by the liver, muscle, and adipose tissue, a phenomenon explained by higher levels of circulating insulin and glucose that are generated. In contrast, the brain continues to use glucose, its major oxidative fuel, at a constant rate. GLUT-1 and GLUT-3 transporters facilitate brain glucose uptake (i.e., transport across the blood-brain barrier) into neurons, respectively) independent of insulin (see Chap. 8).³²

While the metabolic changes that follow glucose ingestion have been studied extensively, the humoral and substrate responses to protein, fat, and mixed meals have not been as well defined.

FIGURE 1-2. Hepatic glycogen concentration time course throughout a day in which three identical mixed meals are ingested at: 8:00 AM, 1:00 PM, and 6:00 PM.

gested protein in the meal is hydrolyzed by proteolytic enzymes and peptidases in the gastrointestinal tract to amino acids, which are then actively transported across the gastrointestinal epithelium into the portal vein. The absorbed amino acids serve two main functions: they can either be oxidized to yield energy or incorporated into protein. As protein, amino acids are readily accessible to meet later fuel needs, but only at the sacrifice of functioning proteins. Therefore, it is necessary to eat a sufficient amount of protein-containing foods daily in order to maintain whole-body protein mass. The liver removes a large fraction of amino acids that enter portal blood following a meal, particularly the gluconeogenic amino acids. The branched-chain amino acids (leucine, isoleucine, and valine) are more likely to escape hepatic extraction and are removed mainly by muscle.³⁴ This is shown by a switch in the net balance of amino acids across the muscle bed from a net output postabsorptively to a net uptake after feeding. The uptake is most

marked for the branched-chain amino acids. As a result, these amino acids constitute the main substrate for the immediate repletion of muscle nitrogen after protein ingestion. In muscle, branched-chain amino acids have a unique capacity to directly promote net protein accumulation, predominantly by inhibiting protein breakdown and to some extent through stimulation of protein synthesis.^{35,36} Again, the increased secretion of insulin plays a major role in promoting net protein anabolism postprandially when the concentrations of amino acids are elevated following protein feeding. Recent studies have demonstrated that low-dose insulin infusions, recreating the relatively small rise in plasma insulin seen with protein ingestion, lower plasma amino acid concentrations in fasted humans and decrease the rate of net amino acid release from muscle.³⁷ This is accompanied by suppression of the rate of whole-body and muscle protein degradation.³⁸⁻⁴⁰ Whole-body protein synthesis, measured as the nonoxidative disposal of leucine, does not increase,^{38,40} nor does muscle protein synthesis.^{39,41} As a result, the improved body and muscle nitrogen balance that accompany even modest increases in plasma insulin *per se* can be attributed to a specific action of insulin to retard proteolysis. Though no increase in overall protein synthesis has been seen either in the whole body, muscle, or splanchnic tissue in response to physiologic increases in plasma insulin, almost certainly the synthesis of some proteins will have been induced while that of others is repressed. It is noteworthy, however, that the combined presence of hyperinsulinemia and hyperaminoacidemia as is seen during protein feeding not only blocks proteolysis but also stimulates protein synthesis.^{42,43} Carbohydrate in a mixed meal, along with protein, further augments insulin secretion beyond the effect of protein alone. This can further facilitate uptake of amino acids by muscle and enhance protein anabolism. It is noteworthy that some amino acids (e.g., arginine and leucine) are strong insulin secretagogues and after protein meals are ingested, insulin release is stimulated, even when the meal is lacking carbohydrate. Under these conditions glucagon plays a critical biological role in preventing potential hypoglycemia by maintaining hepatic glucose production in the face of hyperinsulinemia.³⁴

Finally, with regard to fat metabolism, insulin has three major anabolic actions that combine to promote net triglyceride accumulation in adipose tissue (Fig. 1-3). Following a fat-containing meal, the triglyceride is hydrolyzed to free fatty acids by lipases in the duodenum, absorbed in the small intestine, and reesterified into chylomicron triglyceride, which then enters the systemic circulation via the lymphatics. Insulin, secreted in response to the carbohydrate and/or protein components of the meal, stimulates lipoprotein lipase (LPL) activity and promotes fat and muscle storage of both exogenously derived triglyceride as well as that produced endogenously.⁴⁴ LPL in the capillary endothelium hydrolyzes triglycerides in chylomicrons and VLDL to free fatty acids, which are then transferred to the adipocyte for reesterification into triglyceride. This effect is complemented by insulin's potent inhibitory effect on hormone-sensitive lipase within the fat cell. This lipase normally catalyzes the hydrolysis of stored triglyceride. By this dual mechanism insulin markedly decreases plasma free fatty acid concentrations and stores fat. Finally, insulin stimulates glucose uptake into the adipocyte by stimulating GLUT-4 translocation from the cytoplasm to the plasma membrane, in a fashion similar to that which occurs in the myocyte. Alpha-glycerophosphate formed from glucose is required for the reesterification of fatty acids into triglyceride. Adipocytes lack glycerol kinase and therefore, unlike liver and kidney, are unable to phosphorylate glycerol directly.⁴⁵

FIGURE 1-3. Fat metabolism in the fed state following a fat-containing mixed meal (top panel) and in the fasted state (bottom panel).

Thus, following a meal, insulin is the primary hormonal factor that controls the storage and metabolism of ingested metabolic fuels. Under conditions of mixed meal ingestion when substrate is available in the form of glucose, amino acids, and free fatty acids, an increase in plasma insulin concentration will augment their net storage as glycogen, protein, and fat, respectively. This is accomplished by the inhibition of glycogenolysis, proteolysis, and lipolysis as well as by facilitating the incorporation of substrates into storage depots. It is noteworthy that the dose-response relationships are such that the processes involving breakdown of energy stores are much more sensitive to insulin than those involved with energy accumulation. Thus, small meals (associated with smaller insulin responses) serve mainly to conserve depots by affecting breakdown, whereas larger meals (and concomitant greater insulin responses) are generally required for the direct stimulation of storage mechanisms.

METABOLISM AFTER AN OVERNIGHT FAST

The period after an overnight fast and preceding the ingestion of the morning meal serves as a useful reference point because it represents the period of transition from the fed to the fasted state. At this time the concentrations of insulin, glucagon, and metabolic substrates that were altered by meal ingestion during the preceding day have returned to baseline, and a relative steady state ensues in which the rate of fuel consumption is closely matched by the release of endogenous fuels from storage depots (Fig. 1-4).

After an overnight fast, the decline in circulating insulin leads to a marked decrease in glucose uptake by peripheral insulin-sensitive tissues (e.g., muscle) and a shift toward the use of free

fatty acids by these tissues that are mobilized from fat stores. Nevertheless, the average adult continues to consume glucose at a rate of 7–10 g/h. Total body stores of free glucose, which exist mostly in the extracellular space, amount to only 15–20 grams or about 2 hours' worth of glucose fuel. However, it is even less than that one takes into consideration a more physiologic excursion from a fasting plasma glucose concentration of ~90 mg/dL to ~70 mg/dL, the lowest level of plasma glucose that allows normal brain function. Thus the maintenance of circulating glucose concentration in the face of this ongoing glucose use, particularly by brain, requires that glucose be produced at rates sufficient to maintain its ongoing consumption. Here again, insulin is the key regulator of the transition from the fed to the fasted state, and as in the fed state the liver is at the center of this adaptive mechanism. Four to five hours after a meal (perhaps longer for a very large meal), the liver begins to break down its stores of glycogen and release it as free glucose. This is accomplished by virtue of a reduction in circulating insulin and is supported by the presence of glucagon in the portal circulation. Both the liver and kidney contain significant amounts of glucose-6-phosphatase, and therefore they are the only organs capable of releasing significant amounts of glucose derived from glycogenolysis or gluconeogenesis into the bloodstream. Muscle tissue, which comprises ~25–30% of body mass and contains most of the body's reserves of glycogen (~300 grams versus ~100 grams in liver under fed conditions), lacks glucose-6-phosphatase and therefore is incapable of directly contributing to the maintenance of plasma glucose concentration.

The hepatic processes that provide most of the glucose needed to meet whole-body glucose requirements consist of glycogenolysis and gluconeogenesis. Recent human ^{13}C NMR studies have demonstrated that net hepatic glycogenolysis and gluconeogenesis

FIGURE 1-4. Whole-body fuel metabolism in the postabsorptive state.

contribute about 50% each to rates of whole-body glucose production during the first several hours of a fast.^{46,47} This relatively high level of gluconeogenic activity early in a fast is consistent with other recent studies demonstrating the importance of the gluconeogenic (indirect) pathway for repletion of hepatic glycogen. This suggests that gluconeogenesis is a life-sustaining process that is never completely suppressed, and that when an individual ingests a meal, gluconeogenic flux is directed into hepatic glycogen stores (indirect pathway) along with contributions from the direct pathway. Once the meal is absorbed, the gluconeogenic flux is redirected toward hepatic glucose delivery.

In the first several hours of a fast the brain consumes more than half (~4–5 g/h) of the glucose produced by the liver, which amounts to about 180 g/d. Other obligate anaerobic tissues consisting of the formed elements of blood (erythrocytes, leukocytes, and bone marrow) and the renal medulla metabolize glucose but convert it primarily to lactate and pyruvate, which recycle back to the liver to form glucose (Cori cycle). About 20% of the glucose utilized daily in this cycle is remade into glucose. It is noteworthy that neither the Cori cycle nor the glucose-alanine cycle in muscle (see below) yields new carbon skeletons for *de novo* glucose synthesis. Rather, they serve an important role for energy and nitrogen (glucose-alanine cycle) transfer between muscle and liver. Operation of these cycles allows the transfer of energy from the liver to the peripheral tissues. The energy for glucose synthesis derived from oxidation of fat in the liver is delivered to the peripheral tissues, where the energy is gained from the metabolism of glucose to lactate.

After an overnight fast the body is in negative nitrogen balance; i.e., the rate of whole-body protein degradation exceeds the rate of whole-body protein synthesis. The amino acids that furnish the nitrogen, measured as urinary nitrogen loss, arise principally from muscle and splanchnic tissues. Organ balance studies⁹ in

overnight-fasted humans have shown that muscle, which represents the major reservoir of body protein, like the whole body, is in negative nitrogen balance as reflected by a net loss of both essential and total amino acids. The splanchnic bed removes many of these amino acids, especially alanine and other gluconeogenic amino acids. Yet despite removing nitrogen from the circulating plasma, splanchnic tissues themselves are in negative protein balance. Indeed, the observed net loss of tissue protein mass is more dramatic from the liver in animals undergoing fasts of short duration.⁴⁸

As a result of the uptake of gluconeogenic amino acids by the splanchnic bed, there is a net transfer of amino acid carbon and nitrogen to liver. This provides carbon for gluconeogenesis and net glucose production by the liver, and nitrogen for ureagenesis. Alanine and glutamine are particularly important in this process. They are released from muscle in amounts (~50% of total amino acid release) that significantly exceed their representation in muscle tissue proteins (~10–13% of total amino acid residues in muscle protein). Alanine is produced in muscle by transamination of pyruvate derived from glucose and the catabolism of other muscle-derived amino acids (e.g., branched-chain amino acids). Glutamate is produced by transamination of α ketoglutarate supplied by the TCA cycle, and glutamine is produced by the action of glutamine synthase adding a second amino group to glutamate.⁴⁹ The intestine uses some of the glutamine taken up by the splanchnic bed as an oxidative fuel.⁵⁰ The amino groups are released into portal blood either as alanine or ammonia. On a molar basis, alanine is the principal amino acid taken up by the liver. Within the postabsorptive liver, alanine carbon is principally converted to glucose. As the alanine carbon backbone is essentially derived from glucose in peripheral tissues, a metabolic “glucose-alanine cycle” operates between the liver and periphery, analogous to the Cori cycle. The glucose-alanine cycle provides a nontoxic alternative to ammonia

for transfer of amino acid groups derived from muscle amino acid catabolism to the liver for conversion to urea. Glutamine is removed by the kidney, as well as by the liver and gut. In the kidney it serves a dual purpose of supplying carbon for renal gluconeogenesis and amino groups for ammoniogenesis. The latter process is of particular importance in maintaining body acid-base balance during fasting.^{51,52} Combined, alanine and glutamine account for more than 40% of the amino acid carbon provided to the splanchnic organs and kidneys for use in glucose production.

Finally, the fall in insulin levels after an overnight fast permits the release of free fatty acids and glycerol from fat stores (Fig. 1-3). This response appears to be more pronounced in visceral than peripheral fat depots (see Chap. 26). While the rate of lipolysis and magnitude of the decline in insulin is of sufficient magnitude to supply extracerebral tissues such as muscle, heart, and liver with free fatty acids and hepatic tissues with glycerol for gluconeogenesis, these changes are not of sufficient magnitude to stimulate appreciably the rate of hepatic conversion of free fatty acid to ketones.

EARLY ADAPTATION TO STARVATION

Since the glycogen stores in the liver are typically limited to approximately 70 grams after an overnight fast, while glucose utilization occurs at a rate of approximately 7–10 g/h, hepatic glycogen stores are largely dissipated early in the course of fasting.^{47,53} Thus the initial phase of starvation is characterized by a relative increase in the rate of gluconeogenesis in order to meet the ongoing tissue demands for glucose (mainly from the central nervous system). The dependence of glucose production on protein stores is reflected by an increase in urinary nitrogen excretion in the early phase of starvation. During the first 24 hours of a fast, urinary nitrogen excretion averages 4–7 g/m² in the absence of nitrogen intake.⁵³ This amounts to approximately 50–75 grams of protein (~1 g N/6.25 g protein) for the average 70-kg person. Similar results are obtained using isotopic tracer methods to estimate total body rates of protein oxidation.⁵⁴ Therefore, regardless of whether simple urinary nitrogen balance is measured or a tracer method is used, the results suggest that about 50 grams of protein are oxidized in the 24 hours following a meal. Since the tissue protein content does not exceed 20% by weight for any tissue, 50–75 grams of protein translates into 250–375 grams of tissue or the equivalent of 1/2–3/4 pound of lean body mass lost on the first day of a fast.

The increase in gluconeogenesis is mediated by adaptations in both hepatic and peripheral insulin-responsive tissues. In muscle, the release of alanine and other glycogenic amino acids increases in conjunction with an acceleration of proteolysis.⁵⁴ At the same time the rate of hepatic conversion of gluconeogenic amino acids into glucose is augmented.⁵⁵ The increase in glucose synthesis from amino acids is not, however, solely due to increased precursor availability, since plasma levels of alanine and other glycogenic amino acids decline.⁵⁶ Taken together, these observations suggest that intrahepatic gluconeogenic mechanisms are stimulated as well, which enhances the efficiency of this process. Recent data suggest that peroxisome proliferator activated receptor α (PPAR α) and the transcriptional coactivator PGC-1 are likely important factors mediating the adaptive response of liver during fasting.^{57,58} An additional factor contributing to glucose homeostasis is the increased release of fatty acids and glycerol from triglyceride stores in adipose tissue and muscle due to activation of hormone-sensitive li-

pase. The increased availability of glycerol provides the liver with an additional substrate for gluconeogenesis. The increased availability of fatty acids to peripheral tissues limits glucose transport into skeletal muscle, thus preserving glucose for the central nervous system and other obligate glucose-utilizing tissues and diminishing the demands for gluconeogenesis and proteolysis. Early *in vivo* studies found that fatty acids reduced insulin-stimulated glucose uptake in isolated cardiac myocytes through a reduction in pyruvate dehydrogenase activity, resulting in an increase in intracellular citrate concentrations and inhibition of hexokinase activity.^{59,60} More recent studies in humans have found that fatty acids cause insulin resistance in skeletal muscle by directly interfering with insulin stimulation of glucose transport activity.^{61,62} Recent data suggest that this is likely occurring through fatty acid activation of a serine/threonine kinase cascade, leading to increased serine phosphorylation of IRS-1/IRS-2, which in turn leads to decreased IRS-1/IRS-2 tyrosine phosphorylation and decreased activation of phosphatidylinositol 3-kinase, a necessary step for insulin-stimulated glucose transport in skeletal muscle.⁶³ This fatty acid-induced decrease in insulin-stimulated glucose metabolism, while protective under fasting conditions, plays an important pathologic role in mediating insulin resistance associated with obesity and type 2 diabetes.

At the same time, the fatty acids in the circulation are also delivered to the liver where they generate energy by undergoing β oxidation. This is accomplished by a fall in the insulin/glucagon ratio in the portal circulation, which inhibits acetyl CoA carboxylase, thereby decreasing intracellular malonyl CoA concentration, which in turn activates carnitine palmitoyl transferase, thereby promoting mitochondrial fatty acid oxidation⁶⁴ (see Chap. 2). In this way both the increase in supply of fatty acids and the activation of enzymes of the fat oxidation pathway are synchronized. Thus oxidation of fatty acids by muscle spares glucose for use by the central nervous system, whereas their oxidation by the liver serves to activate gluconeogenesis by furnishing the energy and reducing power required for glucose synthesis.

The metabolic adaptations in the early stages of starvation (namely increased gluconeogenesis, proteolysis, and lipolysis) coincide with and are mainly orchestrated by a decline in insulin secretion below levels seen in the overnight fasted condition, as well as by a modest increase in portal vein glucagon concentrations. Insulin deficiency promotes all aspects of the metabolic response, whereas the effect of glucagon is confined to the liver. Specifically, the decline in insulin promotes protein and fat breakdown and the delivery of gluconeogenic amino acids from muscle and glycerol from fat stores to the liver, while the activation of intrahepatic gluconeogenic processes is promoted by both the rise in glucagon and fall in insulin in the portal circulation. Hypoinsulinemia further contributes to glucose homeostasis by reducing glucose metabolism by extracerebral tissues (e.g., muscle) and by increasing the availability of fatty acids for oxidative metabolism by muscle and liver and ketones for muscle and the central nervous system (Fig. 1-5).

TRANSITION FROM BRIEF TO PROLONGED FASTING

As the duration of fasting progresses, the body shifts from utilization of protein for gluconeogenesis to utilization of fat for ketogenesis and the brain shifts from oxidation of glucose to oxidation of β -hydroxybutyrate and acetoacetate to meet most of its energy requirements^{4,66} (Fig. 1-5). From examination of the potential ener-

FIGURE 1-5. Whole-body fuel metabolism in the fasted state.

stores (Table 1-1) it is clear that a fasting human could survive for only a few weeks if he/she was totally dependent on protein utilization to meet whole-body energy as well as glucose requirements, and therefore a major reduction in nitrogen metabolism must take place in order to allow for prolonged survival.^{4,66} This alteration in substrate utilization is reflected in urea and ammonia excretion data in humans undergoing a prolonged fast; in these subjects urea excretion decreases from 10–15 g/d during the initial days of a fast to less than 1 g/d after 6 weeks of fasting.^{66,67} Since urea is the major osmolyte in the urine that requires excretion, this reduction in urea production lessens the amount of obligatory water excretion and therefore decreases the daily water requirement during a prolonged fast. The increase in ketone production by the liver, together with the capacity of the brain to utilize the increased levels of ketones in the circulation, permits humans to extend their survival time during a prolonged fast from weeks to months as long as an adequate water supply and fat stores are available.^{68,69} During this transition the liver decreases its rate of gluconeogenesis, mostly due to diminished substrate delivery,⁶⁷ while the kidney increases its contribution, which may reach as much as 40% of whole-body glucose production.⁶⁶ The latter most likely represents an adaptive process that allows the body to handle the excess protons generated from fat oxidation. Under these conditions the excess protons are converted to ammonia in the kidney and excreted in the urine. In fact, previous studies have shown increased renal gluconeogenesis during acidosis and a strong correlation between ammoniogenesis and gluconeogenesis.⁵² During the first few weeks of a fast, plasma alanine levels fall markedly to less than one-third of postabsorptive concentrations due to a marked fall in muscle alanine release⁷⁰ (Fig. 1-6). This amino acid as well as lactate are the principal substrates for hepatic gluconeogenesis. The fact that substrate availability is lim-

iting for gluconeogenesis during a prolonged fast has been demonstrated by a rise in plasma glucose concentration following an infusion of small amounts of alanine under these conditions.⁷⁰

In contrast to alanine, the plasma levels of fatty acids double in the first 3–7 days of fasting, after which they remain stable^{65,66} (Fig. 1-6). The increased delivery of fatty acids to the liver facilitates a marked acceleration of hepatic ketogenesis that occurs in the first few days of fasting (see Chap. 2). Peak rates of ketone production (approximately 100 g/d) are achieved by the third day, and are

FIGURE 1-6. Time course for substrates (glucose, alanine, free fatty acids, β -hydroxybutyrate, acetoacetate) and urea nitrogen excretion during a prolonged fast.

maintained thereafter.^{66,69} Despite relatively stable rates of ketone production by the liver, the circulating levels of ketoacids continue to rise throughout the next few weeks as their extraction by peripheral tissues progressively declines.⁷¹ As a result, the central nervous system is supplied with an increasing supply of these water-soluble fat-derived substrates, which eventually account for over one-half of the brain's energy requirements.⁵ The following sequence of events is orchestrated by the accompanying changes in insulin and glucagon concentrations produced during fasting: (1) accelerated delivery of fatty acids from adipose tissue; (2) increased hepatic oxidation of the fatty acids delivered from the circulation, which leads to the formation of keto acids ("ketogenic capacity"); and (3) a reduction in the removal of ketones by peripheral tissues.^{72,73} Hypoinsulinemia activates each of these steps, whereas glucagon plays a key role by enhancing the ketogenic capacity of the liver. In this way ketones ultimately supplant the brain's dependency on glucose and thus provide a means of limiting the brain's gluconeogenic demands, thereby preserving protein stores, a factor critical for survival. In addition, the metabolism of ketones can provide a significant proportion of the energy demands of other body tissues, especially the heart and skeletal muscle.⁴ It has been suggested that the use of such lipid-derived fuels during prolonged starvation may be directly linked to the conservation of body protein stores;⁷⁴ however, the precise mechanisms underlying protein sparing in the face of hypoinsulinemia remain to be elucidated. As the fast progresses and fat stores are depleted, leptin levels also decrease, which serves as another protective signal to the body.⁷⁵ This decrease in leptin concentration has a profound effect on neuroendocrine function and the gonadal axes, which results in a decrease in LH/FSH oscillations and anovulation. In this way nature protects the starving mother from the additional nutritional demands associated with pregnancy in times of famine.

In summary, the body has evolved powerful adaptive mechanisms that ensure an adequate substrate supply in the form of glucose and ketones to the brain at all times, including times of prolonged fasting, to ensure adequate CNS function. Even under the most strenuous conditions of a prolonged fast, humans do not experience loss of consciousness from decreased substrate supply to brain. Instead, death under these conditions typically occurs when fat stores are depleted and protein breakdown is of sufficient magnitude to cause severe respiratory muscle protein wasting, which in turn leads to atelectasis and terminal pneumonia.⁷⁶

ENERGY METABOLISM DURING AND FOLLOWING RECOVERY FROM EXERCISE

Muscle energy requirements during intense exercise can increase by over 10-fold. This increased energy demand is met by mobilizing energy stores locally from muscle glycogen and triglyceride, as well as systemically from liver glycogen and adipose tissue triglyceride (see Chap. 31). Depending on the intensity of the activity, these substrate supplies are used in differing amounts. If the power demands are great (e.g., running a sprint), anaerobic metabolism of muscle glycogen meets the need for rapid supply of energy, whereas if the power requirements are low, such as when jogging, most of the energy requirements are met by oxidation of fat and glucose derived from the circulation. Overall, muscle derives two molecules of ATP for every molecule of glucose from muscle glycogen or glucose that is glycolyzed to lactate, and ~8 molecules of ATP when glucose is metabolized to pyruvate and con-

verted to alanine. While anaerobic metabolism of glucose by muscle produces only a fraction of the 38 molecules of ATP generated when glucose is completely oxidized, it has the major advantage of being able to provide energy more quickly to meet the increased metabolic demands of an intense workload even before oxygen, glucose, or fatty acid delivery from blood increases. However, because of its inherent inefficiency muscle glycogen stores are rapidly depleted by even brief periods of anaerobic metabolism, limiting the type of activity to providing short bursts of energy.

During aerobic exercise of longer duration, glycogenolysis and gluconeogenesis in the liver supply sufficient glucose to the muscle to account for approximately 40% of the increase in fuel consumption with free fatty acids providing the remainder.^{77,78} As the duration of exercise lengthens, glucose utilization by the muscle declines and fatty acid oxidation progressively increases, becoming the dominant oxidative fuel. Glucose uptake by exercising muscle can increase 7- to 40-fold; however, circulating glucose remains relatively stable with hepatic glucose production rising to match the increased need. An increase in portal vein glucagon concentration in conjunction with a decline in portal vein insulin concentration is the main signal for this increased hepatic glucose production. Studies performed in exercising, hepatically denervated dogs suggest that activation of the sympathetic nervous system is not essential for the maintenance of accelerated rates of glucose production during exercise.⁸⁰ The increase in muscle glucose uptake is accompanied by an exercise-induced translocation in GLUT-4 transporters from the cytoplasm to the plasma membrane that is insulin independent^{81,82} and likely mediated by activation of AMP kinase.⁸³ As liver and muscle glycogen stores are typically depleted after a few hours of exercise, with time hepatic gluconeogenesis becomes more important for maintaining these high rates of hepatic glucose production. Alanine and lactate derived from the glucose-alanine cycle and the glucose-lactate cycle provide substrate for this increased hepatic gluconeogenesis.⁷⁸ In addition, these cycles play an important role in redistributing glycogen from resting muscle to exercising muscle during and after prolonged exercise. After prolonged arm exercise, release of lactate by leg muscle is six- to sevenfold greater than in the preexercise basal state.⁸⁶ Similarly, after leg exercise, output of lactate by forearm muscle increases.⁷⁸ These studies suggest that the glucose-lactate cycle redistributes glycogen from resting muscle to fuel those muscles in use during prolonged exercise.⁸⁷ During recovery, muscle glycogenolysis and lactate release from previously resting muscle continue and lactate is cycled to the liver where it is converted to glucose so it can be subsequently taken up by recovering muscle, thereby replenishing glycogen stores in previously exercised muscle.^{87,88} In this way the body ensures an adequate supply of emergency fuel for the next fight-flight response.

IMPACT OF DIABETES ON FUEL HOMEOSTASIS

The metabolic derangements associated with diabetes largely reflect the magnitude of the deficiency in insulin concentration and/or insulin action present. Mild deficiency leads to an impairment in the capacity to effectively increase the storage of ingested fuels (e.g., postprandial hyperglycemia), whereas in its most severe form the deficiency causes a marked acceleration of catabolic processes, including gluconeogenesis, lipolysis, ketogenesis, and proteolysis. In the latter circumstance, the catabolic state in a hyperglycemic patient with insulin-dependent diabetes actually

resembles that seen in starving nondiabetic subjects with reduced glucose levels and thus may be viewed as a state of accelerated starvation. This should not be surprising considering that the hormonal milieu of diabetes and starvation share common features, namely, insulin deficiency in conjunction with relative or absolute glucagon excess.

Fed State

As reviewed earlier, the ingestion of glucose triggers a variety of homeostatic responses in nondiabetic subjects (suppression of hepatic glucose production, stimulation of glucose uptake by hepatic and peripheral tissues), all of which serve to minimize the rise in circulating glucose concentrations. Because these responses are to a large extent dependent on insulin action, diabetes, even in its mildest forms, is invariably accompanied by postprandial hyperglycemia.

In diabetic patients who retain some capacity for endogenous insulin secretion [e.g., type 2 diabetes mellitus (T2DM)], postprandial hyperglycemia is closely related to the fasting glucose level and is accounted for both by a delay in the suppression of endogenous^{89,90} and by an impaired ability of peripheral tissues to remove the glucose released from the splanchnic bed, reflecting defects in insulin action in both hepatic and peripheral tissues^{91,92} (see Chaps. 24 and 25). However, the magnitude of the postprandial glucose excursion is generally less pronounced in T2DM compared to that seen in untreated type 1 diabetes mellitus (T1DM) patients who lack functioning β cells. The absence of an insulin portal-peripheral gradient in T1DM leads to a more severe derangement,

particularly at the level of the liver, which is manifest by a gross defect in suppression of hepatic glucose production following glucose ingestion.⁹³ Moreover, the liver of the patient with T1DM fails to appropriately take up glucose in response to a rising circulating glucose level. This is manifest by a severe defect in the capacity of the liver to store glucose as glycogen following meal ingestion as has recently been demonstrated by NMR spectroscopy in T1DM patients.¹⁷ This increases delivery of glucose to peripheral tissues, where the capacity of muscle (and adipose) tissue to remove glucose is also severely compromised by the lack of an insulin secretory response, as well as by the development of impaired insulin action resulting from chronic insulin deprivation and hyperglycemia (glucose toxicity).^{94,95} The multifaceted nature of the disturbance (i.e., liver plus periphery) in the T1DM patient leads to a gross defect in the efficiency of metabolic glucose disposal. The resulting hyperglycemia is partially "compensated" for by increased renal glycosuria.

The diabetic state also leads to impaired metabolic handling of ingested protein and fat. After protein ingestion, postprandial elevations of circulating amino acids are exaggerated in T1DM patients, mainly due to increased levels of branched-chain amino acids.³⁴ This is largely due to a reduction in the net uptake of branched-chain amino acids by muscle tissue, a finding consistent with the known capacity of insulin to inhibit the release of branched-chain amino acids from muscle.^{37,39} Protein feeding also alters glucose homeostasis in insulin-deficient T1DM subjects due to amino acid stimulation of glucagon release that is not matched by an increase in portal vein insulin. As a result hepatic glucose production, and in turn plasma glucose, increases. Finally, the ingestion of fat-containing foods may lead to increased or prolonged

FIGURE 1-7. Whole-body fuel metabolism in diabetic ketoacidosis.

elevations of plasma triglycerides in both T2DM and T1DM patients because of defective triglyceride removal (see Chap. 47). This is because the disposal of exogenous triglycerides (packaged in chylomicrons) is mediated by the activity of the insulin-sensitive enzyme lipoprotein lipase.⁴⁴ The alteration in triglyceride removal is most evident during ingestion of mixed meals, when the discrepancies between insulin levels in nondiabetic and diabetic individuals are most pronounced. Taken together, these observations suggest that the scope of the metabolic disorder associated with insulin deficiency or deficient insulin action during feeding may not be restricted to glucose intolerance, but may involve protein and fat intolerance as well.

Fasted State

The presence of relative or absolute insulin deficiency after an overnight fast leads to an elevation of circulating glucose levels in the basal state. In patients with T2DM, fasting insulin concentrations may be normal or even elevated, but only because of insulin resistance and at the expense of fasting hyperglycemia. In such patients, hepatic glucose production is generally elevated in proportion to the magnitude of the hyperglycemia.⁹⁵ In patients with T1DM, portal insulin deficiency is more pronounced and this, in conjunction with ongoing glucagon secretion, consistently increases hepatic glucose production (see Chap. 7). Because glucose uptake in the fasting state mainly takes place in non-insulin-sensitive tissues (e.g., the brain), total body glucose uptake actually tends to be increased (due to the mass action effect of hyperglycemia), underscoring the key role of the liver in determining the fasting glucose level in diabetes.

Increased rates of hepatic glucose production in both T2DM and T1DM can be attributed to increased rates of gluconeogenesis,⁹⁶ which may be due to both intrahepatic mechanisms and increased substrate delivery through recycling of gluconeogenic precursors (e.g., lactate, alanine, and glycerol).^{91,94-97} The former changes can be mostly attributed to decreased portal vein insulin:glucagon ratios, whereas the latter changes are to a large extent attributable to accelerated fat mobilization. Insulin deficiency leads to the generation of glycerol from activation of lipolysis that is used by the liver for gluconeogenesis and to the generation of free fatty acids, which impair glucose oxidation in muscle, thereby promoting the recycling of lactate and pyruvate to the liver.⁶¹

In the extreme situation of complete β -cell failure, an ever-increasing fasting plasma glucose concentration fails to elicit a secretory response (Fig. 1-7). This hyperglycemia, glycosuria, and volume depletion stimulate the secretion of a variety of counterregulatory hormones (glucagon, catecholamines, growth hormone, and cortisol), which greatly augment hepatic gluconeogenesis and ketogenesis, which in turn result in glucose and ketone overproduction.^{98,99} (see Chap. 9). Under these conditions, the breakdown of protein and triglyceride stores is dramatically increased, leading to the accelerated delivery of amino acids, lactate, glycerol, and free fatty acids to the liver, where under the influence of hyperglucagonemia and increased free fatty acid oxidation they are rapidly converted to glucose and ketones. Because of the combined effects of hypoinsulinemia and insulin resistance produced by the elevated levels of counterregulatory hormones, compensatory increases in glucose removal (other than renal) virtually cease.^{100,101} The clinical correlate of this sequence of events is profound hyperglycemia and hyperketonemia, as is observed in diabetic ketoacidosis (see Chap. 34).

Ketogenesis

J. Denis McGarry

Daniel W. Foster

PHYSIOLOGICAL AND CLINICAL OVERVIEW

In the normal, fed state the ketone bodies, acetoacetic acid and 3-hydroxybutyric acid, play little role in body metabolism. Production rates by the liver and plasma concentrations are low. The primary circulating substrates are diet-derived glucose and mobilized free fatty acids (FFA). On the other hand, if food is unavailable, the ketones rapidly take on major importance as an alternative energy source, particularly for the brain.¹ It is a peculiarity of the central nervous system that it cannot use plasma FFA as a metabolic fuel, in contrast to most other tissues in the body. Because the great bulk of stored energy is in the form of triglyceride contained in the adipose tissue mass (and because reserve stores of carbohydrate in the form of glycogen are extremely limited, sufficient to sustain energy needs for less than 24 hours), it follows that a mechanism to convert fat into a form of substrate the brain can use for energy is critical. The process involved is *ketogenesis*, the conversion of long-chain fatty acids into acetoacetate and 3-hydroxybutyrate by the liver. These four-carbon substrates protect the central nervous system in two ways, one directly and the other indirectly. Directly, the brain oxidizes the ketoacids so efficiently that normal function is unimpaired even in the face of plasma glucose levels sufficient to cause sweating, nervousness, chest pain, and mental confusion, provided plasma ketone concentrations are in the low millimolar range. Indirectly, acetoacetate and 3-hydroxybutyrate are used effectively in a variety of other tissues (together with FFA), preempting their need for glucose and thereby conserving the hexose for use by the brain.² It is clear, therefore, that the primary utility of ketogenesis is to provide universally oxidizable substrate for energy purposes.

Two other functions of the ketoacids have also received attention. On the basis of the observation that infusion of 3-hydroxybutyrate results in diminished urinary nitrogen loss in starved humans, it has been widely assumed that the ketones somehow limit muscle breakdown, thereby providing protection against the deleterious effect of a prolonged negative nitrogen balance. Two mechanisms have been assumed. First, by limiting demands for glucose as described previously, the drive for gluconeogenesis (which of necessity is fueled by muscle amino acids) is diminished. Second, ketone bodies have been thought to have a direct inhibitory effect on proteolysis in muscle. However, it has been shown that although sodium acetoacetate diminishes amino acid release from muscle, free acetoacetic acid does not. Because

sodium bicarbonate sufficient to produce the same alkalinizing effect as sodium acetoacetate also diminishes amino acid release, it may turn out that the anions derived from the ketoacids have a regulatory effect on muscle breakdown. The only other known function of acetoacetate and 3-hydroxybutyrate is as precursors for lipid synthesis in the cerebral tissue of neonates.³

Although the increased production of acetoacetate and 3-hydroxybutyrate that characterizes starvation is a beneficial adaptive response, larger accumulations of ketones are dangerous. This is because they are powerful organic acids capable of producing a profound metabolic acidosis. This point is illustrated by the fact that untreated diabetic and alcoholic ketoacidoses, the major pathologic ketotic states, are potentially fatal illnesses. The physiological ketosis of fasting or prolonged starvation, on the other hand, never progresses to a life-threatening acidosis. The pathologic transition is prevented by the presence of an intact pancreatic β cell (Fig. 2-1). When plasma FFA and ketone concentrations rise, there is a modulation of free fatty acid mobilization from adipose tissue. The major mechanism is probably a fatty acid and ketone-induced stimulation of insulin release from the pancreas, which serves to attenuate lipolysis,^{4,5} although a direct antilipolytic effect of ketone bodies on the adipocyte has also been postulated. In any event, ketogenesis is limited because of insufficient fatty acids to allow maximal rates of ketone production in the liver; thus a metabolic acidosis does not occur.

In the sections that follow, current understanding of the mechanisms by which ketogenesis is controlled will be discussed in some depth. Because the system is complicated, it may be helpful to give a brief anticipatory summary at this point. Details will subsequently be added.

It has already been pointed out that the substrate for ketone body formation is long-chain fatty acids. These fatty acids are ordinarily derived from adipose tissue but can also arise from hepatic triglycerides. For practical purposes (in the absence of certain inborn errors of amino acid metabolism such as maple syrup urine disease), accelerated ketone body production does not occur unless the rate of FFA delivery to the liver is increased. On the other hand, increased fatty acid delivery alone is not sufficient to induce rapid ketogenesis; the second necessary component is an activation of hepatic fatty acid oxidative capacity. The required changes in adipose and hepatic tissues are initiated by alterations in plasma concentrations of glucagon and insulin: a low glucagon:insulin ratio, characteristic of the fed state, inhibits free fatty acid release from

SIMPLE STARVATION

TYPE I DIABETES

FIGURE 2-1. Feedback control of ketogenesis during fasting by insulin. As described in the text, the ketogenic sequence is initiated by a fall in plasma insulin and a rise in plasma glucagon. Free fatty acids are mobilized from adipose tissue stores and transported to the liver, which has been activated for ketone body production. In simple starvation, as plasma fatty acid and ketone concentrations rise, insulin release from the pancreas is stimulated. This blunts (but does not normalize) lipolytic activity in the fat cell such that plasma free fatty acid levels are fixed at about 0.7–1.0 mmol—sufficient to allow moderate production of acetoacetate and 3-hydroxybutyrate by the liver, but insufficient to allow the maximum rates of production required to develop ketoacidosis. In type I diabetic subjects, the protective insulin feedback loop cannot operate because of β -cell destruction in the islets of Langerhans. As a consequence, plasma FFA reach much higher concentrations, driving ketone production to maximal rates, thereby leading to the ketoacidotic state. Experimentally, ketone bodies can directly suppress lipolysis, but this is likely of lesser importance because FFA levels are very high in diabetic ketoacidosis despite markedly elevated ketone concentrations.

adipose tissue stores and deactivates the β -oxidative sequence for free fatty acids, which controls the ketogenic rate in the liver. Change to a high glucagon: insulin ratio, as occurs in fasting or diabetes, is characterized by enhanced lipolysis and activation of hepatic fatty acid oxidation. In the liver, a critical factor is the level of malonyl CoA, the first committed intermediate in long-chain fatty acid synthesis. When malonyl CoA concentrations are high, rates of fatty acid oxidation are repressed through inhibition of the carnitine palmitoyl transferase I (CPT I) reaction. This enzyme regulates entry of FFA into the mitochondrion and thus controls ketogenesis. Conversely, when malonyl CoA levels are low, derepression of the transferase allows ketogenesis to proceed at rates directly proportional to delivery of the fatty acyl substrate. Put in other terms, activation of the ketogenic machinery by a fall in malonyl CoA concentration shifts the control of ketogenesis from

the hepatic enzymic machinery to the rate of delivery of free fatty acids.

It is critical to understand that the liver is fully operational for acetoacetate and 3-hydroxybutyrate formation after a short period of fasting (i.e., there is little difference in the potential for ketone body synthesis between a short fast and completely uncontrolled diabetes). The severe ketoacidosis seen in the latter state (and in alcoholic ketoacidosis) is due solely to plasma fatty acid concentrations much higher than those seen during a fast. In the diabetic state limitation of lipolysis is precluded by the inability of the pancreas to respond to rising FFA and ketone levels with appropriate release of insulin; in alcoholic ketoacidosis, alteration of FFA release from fat depots in response to hormones appears to be abnormal. Interactions between fat metabolism in adipose and hepatic tissues should become clearer from the discussion that follows.

RELATIONSHIP BETWEEN ADIPOSE TISSUE AND LIVER IN KETOGENESIS

As noted previously, the primary substrate for ketone body formation is free fatty acids. Although under certain circumstances these may be derived from hepatic triglycerides, their major source is adipose tissue. Because it can be easily shown that a precursor-product relationship exists between plasma free fatty acids and circulating ketone bodies, it was initially felt that rates of hepatic ketogenesis were simply the passive consequence of the rate of delivery of free fatty acids to the liver. According to this formulation no regulatory control was exerted in the hepatocyte, which remained poised to make ketones once substrate became available. Supporting evidence for this view came from the experimental observation that if the triglyceride stores of adipose tissue were depleted by systematic semistarvation, acute ketosis disappeared in rats made diabetic by pancreatectomy.⁶ It was also noted that in the mild ketosis (2–5 mmol) of starvation, plasma free fatty acid concentrations were generally around 1 mmol,⁷ although in full-blown ketoacidosis ketone concentrations in the range of 17–20 mmol were accompanied by fatty acid levels of 2–4 mmol.⁸ On the basis of these observations, the simple lipolytic theory for the control of ketogenesis became broadly accepted.

It subsequently became apparent that such a theory was inadequate. Three major observations indicated that a substantial change in the pattern of liver metabolism was also required for ketogenesis to attain maximal rates. First, FFA levels in plasma could be elevated *in vivo* to levels equivalent to those seen in diabetic ketoacidosis without inducing ketosis in normal animals.^{9,10} Second, developed ketosis could be reversed under circumstances in which plasma FFA concentrations were kept high and unchanged.^{11,12} Third, and most important, if livers were removed from normal, fed rats and perfused with high concentrations of oleic acid, production of acetoacetic and 3-hydroxybutyric acids was only minimally stimulated. On the other hand, livers taken from fasted or diabetic animals, given the same concentration of oleic acid, produced ketone bodies at rates five- to tenfold higher than those seen in non-ketotic rats.¹³ It thus became clear that biochemical changes were required in both adipose tissue and liver for major ketogenesis to supervene. Conceptually, adipose tissue would be considered the substrate storage site, and liver would represent the conversion ma-

chinery. As will become apparent in the subsequent discussion, regulation of the two sites can occur in coupled or independent fashion. Activation of each is necessary, but not sufficient, to induce maximal ketogenic rates.

HORMONAL CONTROL OF KETOGENESIS

For many years it was thought that a relative or absolute deficiency of insulin was in itself sufficient for full activation of the ketogenic process. After all, insulin deficiency was known to be a characteristic of diabetes mellitus, and it had long been recognized that plasma insulin concentrations fell with the progression of a fast in inverse proportion to the rise of plasma ketones.⁷ That this formulation might be oversimplified was suggested by two sets of observations. First, Unger¹⁴ showed that diabetes was characterized not only by insulin deficiency, but by a relative or absolute excess of glucagon; therefore it was a bihormonal metabolic disorder. Second, a series of experiments carried out *in vitro* indicated that the α cell hormone had ketogenic activity in isolated liver preparations.^{15,16} The roles of the two hormones in the ketogenic process were then examined using intact rats as the experimental model.¹⁷ Fed, nonketotic animals were infused with either anti-insulin serum (AIS) or glucagon for short periods of time (1–3 hours). AIS infusion rapidly produced severe hyperglycemia, elevated plasma levels of FFA, and a prompt rise in plasma ketones. Thus by binding to insulin and preventing its biologic activity, AIS induced a state of early diabetic ketoacidosis. Glucagon, by contrast, caused only a minimal elevation of plasma glucose concentrations and no change in FFA or ketone body levels. Although glucagon is known to be a potent initiator of glycogenolysis in the liver (glycogen stores in these rats were dissipated), it did not cause hyperglycemia. The reason is quite straightforward. As glycogenolysis supervened, a transient rise in plasma glucose occurred, which in turn stimulated insulin release from the pancreas. This insulin accelerated the efficient disposition of glucose in muscle and adipose tissue; in effect, glucagon caused transfer of stored carbohydrates from liver to peripheral tissues in the absence of hyperglycemia.

Up to this point the findings were not unexpected, and were fully in accord with predictions. The second part of the experiment, however, produced results that elucidated the independent roles of insulin and glucagon in the regulation of ketogenesis. At the end of the infusion periods, livers were removed from the experimental animals and placed in an *in vitro* perfusion system. Oleic acid was added to bring the FFA concentration to 0.7 mmol in the perfusion media, approximately the level seen with fasting. Under these circumstances, livers taken from animals treated with AIS produced ketone bodies at an accelerated rate when compared with control livers from nontreated animals. This was fully expected, because the livers were taken from animals that were ketotic *in vivo*. Surprisingly, however, perfusion of livers from glucagon-treated animals (which were not ketotic) produced acetoacetate and 3-hydroxybutyrate at rates comparable to those in animals made experimentally diabetic. Thus, a ketogenic liver had been produced in a nonketotic animal. Measurements of hormones in plasma showed that in AIS-treated rats, insulin concentrations were low and glucagon concentrations were high. In the glucagon-treated animals, levels of the α -cell hormone were elevated into the patho-

FIGURE 2-2. Bihormonal model for the control of ketogenesis. (Reprint with permission from the American Diabetes Association, Inc., from McGarry JD: Lilly lecture. *New perspectives in the regulation of ketogenesis*. *Diabetes* 1979;28:517.)

physiologic range, but in contrast to the AIS experiment, plasma insulin levels were also high. The latter observation meant, contrary to the generally held view, that the switch in the metabolic profile of the liver to fatty acid oxidation and ketone formation did not require an insulin-deficient state *in vivo* for its induction.

Why was the glucagon-treated animal not ketotic? The answer turned out to be quite simple: It was deficient in substrate. Recall that measured FFA concentrations after glucagon were low; this was because glucagon-induced hyperglycemia had produced an insulin response and insulin has a powerful antilipolytic effect. Correctness of this interpretation was proved by showing that experimental elevation of plasma FFA concentrations caused the glucagon-treated animals to develop a brisk ketosis. It was then proposed¹⁷ that the hepatic ketogenic machinery was under the same bihormonal control as had been postulated for glucose homeostasis by Unger.¹⁴

Current understanding of the system, based on the previous mentioned experiments, is shown in Fig. 2-2. According to this model, insulin deficiency acts primarily at the level of the adipocyte to provide long-chain fatty acid substrate for ketone body formation in the liver; in the presence of insulin, lipolysis is blocked and ketosis does not occur because of substrate deficiency. Glucagon, on the other hand, is thought to act primarily on the liver to activate fatty acid oxidation and ketone formation at the expense of triglyceride synthesis. Although emphasis has been placed on the independent roles of insulin and glucagon, it should not be concluded that insulin deficiency has no effect on the liver. Considerable evidence has accrued to indicate that the glucagon:insulin ratio is more important than absolute concentrations of either hormone in determining metabolic events within the hepatocyte. It should also not be inferred that insulin and glucagon are the only hormones involved in the regulation of ketogenesis. Although they doubtless represent the primary signals, a variety of other hormones, particularly catecholamines, have been shown to exert effects similar to those of glucagon.

Does the model developed in the rat apply to humans? The evidence is quite strong that it does. For example, Gerich and associates¹⁸ showed that hyperglycemia and ketonemia in type 1 diabetic patients withdrawn from insulin were almost completely inhibited when glucagon secretion was blocked by infusion of somatostat-

Further, it was shown that diabetic subjects pretreated with glucagon had enhanced ketogenic responses compared with control subjects given the same level of infused fatty acids.¹⁹ Finally, patients with glucagon-producing tumors have small but definitely increased ketone concentrations as a consequence of their disease.²⁰ It thus seems safe to conclude that the overall thrust of the model is correct.

BIOCHEMICAL ASPECTS

The enzymatic pathway for the production of acetoacetate and 3-hydroxybutyrate can conveniently be divided into two sections. The first, collectively called the β -oxidative sequence for fatty acid oxidation, involves the generation of acetyl CoA from long-chain fatty acids. The second concerns the synthesis of the two ketones from acetyl CoA. Four enzymes are involved in the latter portion of the pathway, as indicated by the following reactions (called the HMG-CoA cycle):

Reactions 1 through 4 are catalyzed by the enzymes acetoacetyl CoA thiolase (E.C.2.3.1.9), HMG-CoA synthase (E.C.4.1.3.5), HMG-CoA lyase (E.C.4.1.3.4), and D-3-hydroxybutyrate dehydrogenase (E.C.1.1.1.30), respectively. All are located in the mitochondria. The rate-limiting enzyme is considered to be HMG-CoA synthase, which is present in high concentrations only in liver mitochondria. The other three enzymes are found in significant quantities in a variety of extrahepatic tissues. (Note that most tissues contain another isoform of HMG-CoA synthase in the extramitochondrial compartment, but this is involved in the process of cholesterol biosynthesis.) It had become clear by the late 1960s that neither the amount nor the activity of these enzymes changed sufficiently to account for the increased ketogenic capacity of the liver in ketotic states. Other studies focused on alternative routes of acetyl CoA disposal as playing a key role. Thus, it was considered that a deficiency of oxaloacetate (thought to be characteristic of all ketotic states) diverted acetyl CoA from citrate formation to the ketogenic sequence. Although disposal of acetyl CoA can, under certain circumstances, modulate absolute rates of ketone formation, it was possible to show that high rates of ketone synthesis can be produced in situations where tricarboxylic acid cycle activity is not suppressed, but stimulated. These experiments indicated that the primary regulatory role was not exerted through alterations in acetyl CoA disposal, but rather by changes in the series of reactions leading to the generation of acetyl CoA from long-chain fatty acids.

As shown in Fig. 2-3, when a long-chain fatty acid is taken up by the hepatocyte it has two major routes of metabolism. Either it

FIGURE 2-3. Fatty acid metabolism in the liver. Fatty acids are taken up by the liver in concentration-dependent fashion. Following esterification to coenzyme A, the fatty acid may be utilized for triglyceride (and phospholipid) formation and leave the liver as very low density lipoproteins. Alternatively, fatty acyl CoA can be transported inside the mitochondrion for oxidation to ketone bodies and CO_2 . Transport across the inner mitochondrial membrane requires esterification to carnitine under the influence of the enzyme carnitine palmitoyl transferase I (CPT I) present on the outer membrane. This reaction appears to be the rate-limiting step for fatty acid oxidation and ketogenesis. Inside the mitochondrion, the acyl CoA derivative is reformed under the influence of carnitine palmitoyl transferase II (CPT II). The capacity for fatty acid oxidation is fixed and large relative to activity of the Krebs tricarboxylic acid cycle. Therefore, the bulk of fatty acids entering the matrix will be converted into ketone bodies.

can be esterified with glycerol-3-phosphate to form triglycerides (and phospholipids) or it enters the mitochondrion for oxidation to acetyl CoA and ketone bodies. In the fed, nonketotic state, the bulk of fatty acids traverse the esterification pathway. With fasting or diabetes, the distribution changes as ketone body production is accelerated; a much larger fraction of the fatty acids taken up enter the oxidative pathway at the expense of esterification.¹³ It was initially believed that regulation was exerted on the esterification wing of the pathway, but this was disproved in an experiment wherein fatty acid oxidation was blocked acutely in the perfused liver by the inhibitor (+)-decanoylcarnitine, with the result that flux of fatty acids into esterification was immediately restored to normal.²¹ This experiment indicated that there was nothing intrinsically wrong with the esterification sequence and strongly suggested that primary control of ketogenesis was exerted on the oxidative pathway. The site of such control was initially deduced from studies comparing the metabolism of oleic acid (representative of long-chain fatty acids) and the medium-chain fatty acid, octanoate.^{13,22} Coenzyme A derivatives of long-chain fatty acids are unable to penetrate the inner mitochondrial membrane. For transfer to occur there must be an esterification with carnitine, a reaction catalyzed by the enzyme carnitine palmitoyl transferase I (CPT I). Long-chain fatty acyl CoA is resynthesized by a reversal of the carnitine esterification reaction inside the mitochondrion under the influence of the enzyme carnitine palmitoyl transferase II (CPT II). In contrast to their long-chain analogues, medium-chain fatty acids are freely permeable across the inner mitochondrial membrane and have no need for esterification to carnitine. When livers from fed and fasted animals were perfused with oleic acid, rates of ketone formation in fasted livers were five- to sevenfold greater than in the control organs. When octanoic acid was used as substrate, ketogenic rates in the two types of liver were equivalent. Moreover, infusion of octanoate into normal fed rats promptly induced ketosis, but long-chain fatty acids had no such effect.²² It thus became clear that the regulatory site was the carnitine palmitoyl transferase system of enzymes, the first specific step in the fatty acid oxidative sequence.

The mechanism whereby this enzyme system is regulated emerged in 1977. Solution of the problem provided understanding not only of the control of ketogenesis, but of two other longstanding observations: the fact that when rates of fatty acid oxidation are high (fasting, uncontrolled diabetes), fatty acid synthesis is low, and the demonstration that ketotic states are always associated with hepatic glycogen depletion. A relationship between glucose and lipid metabolism in the liver was implicit in the observation that starvation ketosis is immediately reversed by the ingestion of small amounts of carbohydrate. The initial hypothesis was that when glucose was available to the liver, a glycolytic metabolite would act to suppress the carnitine palmitoyl transferase step. It was presumed that the concentration of this metabolite would fall in parallel with glycogen stores when the liver was exposed to a high glucagon:insulin ratio. The hypothesis turned out to be correct in principle, but the controlling intermediate was not a participant in the glycogenolytic-gluconeogenic pathway. Rather, it was malonyl CoA, the primary substrate for long-chain fatty acid synthesis, which is derived via citrate from ingested or stored carbohydrate.²³ It was already known that malonyl CoA levels in liver fluctuated in direct proportion to the rate of fatty acid synthesis.²⁴ Its position as the first committed intermediate in long-chain fatty acid synthesis made it an attractive candidate as a regulator of fatty acid oxidation. Thus, when malonyl CoA levels were high, assuring vigorous

fatty acid synthesis, it would be logical to expect that rates of fatty acid oxidation should be low (to avoid a futile cycle of long-chain fatty acid synthesis and breakdown). When added to liver homogenates, malonyl CoA powerfully inhibited the oxidation of oleic acid and did so at physiologically relevant concentrations. The block in fatty acid oxidation was immediately reversed upon removal of malonyl CoA and was not reproduced with other CoA esters such as acetyl CoA, propionyl CoA, or methylmalonyl CoA.²³ When tested with mitochondrial fractions, malonyl CoA was shown to block the oxidation of oleate, palmitate, and palmitoyl CoA (which requires the action of both transferases), but did not inhibit the oxidation of palmitoyl carnitine (which requires only the action of CPT II), or of octanoate (which is carnitine independent).²⁵ In studies with mitochondrial membranes, it was shown directly that only CPT I was inhibited by malonyl CoA and that the inhibitor acts in pseudocompetitive fashion against the long-chain acyl CoA substrate in the reaction.²⁶ The K_i is 1- μ mol both in rat and human (fetal) liver.

Support for the key role of malonyl CoA came from experiments in which rates of fatty acid oxidation were manipulated over wide ranges. Under these circumstances it could be shown that malonyl CoA concentrations followed the predicted course; i.e., when malonyl CoA levels were high, rates of fatty acid synthesis were brisk and fatty acid oxidation was inhibited.²⁷ When malonyl CoA levels were at their nadir, fatty acid oxidation was maximal and fatty acid synthesis ceased. These interrelationships persisted in a smoothly-related fashion as the system was manipulated from one extreme to the other. Such observations meshed nicely with the previously mentioned role of glucagon in inducing ketogenesis and the demonstration that glucagon treatment of intact animals, in its addition to isolated hepatocytes precipitously dropped malonyl CoA concentrations.^{28,29} It is now known that glucagon acts by causing cyclic AMP-mediated phosphorylation of key enzymes in the glycolytic sequence such that citrate concentrations fall, imposing a limitation on substrate available for malonyl CoA formation. In addition, glucagon is thought to inhibit acetyl CoA carboxylase, the enzyme catalyzing the formation of malonyl CoA from acetyl CoA.

As in most metabolic pathways, the primary control mechanism for fatty acid oxidation and ketogenesis (in this case fluctuation in hepatic malonyl CoA levels) is modulated by other regulatory components. Three such factors are now recognized. First, in all ketotic states, hepatic concentrations of carnitine (the transfer molecule for long-chain fatty acids across the membrane restriction barrier) rise to high levels.³⁰ This further accelerates CPT I activity by a mass-action effect. Second, long-chain fatty acyl CoA like glucagon, inhibit acetyl CoA carboxylase, assuring a maximal fall in malonyl CoA generation and an increase in fatty acid oxidation as the liver is flooded with fatty acids secondary to uncontrolled diabetes.³¹ Although glucagon is considered to be the primary regulator of the process, long-chain fatty acyl CoAs function synergistically in a backup role. Third, ketotic states are characterized not only by cessation of hepatic malonyl CoA synthesis, but also by reduced sensitivity of liver CPT I to this inhibitory molecule.³²⁻³⁵ Teleologically, the latter phenomenon might be viewed as an amplification mechanism for control of CPT I activity over and above that imparted simply by changes in tissue malonyl CoA content. Also noteworthy is that upon reversal of the ketotic state (refeeding after a fast or treatment of diabetic animals with insulin) it takes several hours for normal malonyl CoA sensitivity of liv-

CPT I to be restored.^{34,35} This might be nature's way of ensuring that hepatic fatty acid oxidation is not immediately shut down under such conditions, but continues at a rate sufficient to support gluconeogenic carbon flow and thus repletion of hepatic glycogen stores via the so-called indirect pathway.^{35,36} Presumably, under these conditions the fatty acid substrate derives not so much from plasma (as adipose tissue lipolysis is rapidly suppressed by the rising insulin concentration), but from triglyceride stores accumulated in the liver during the prior period of insulin deficiency.

OVERVIEW

Against this background, the overall features of the model, schematically depicted in Fig. 2-4, can now be reviewed.³⁷ With the ingestion of carbohydrate (or an ordinary mixed meal of carbohydrate, fat, and protein), glucagon concentrations are low and insulin concentrations are high, with the result that hepatic malonyl CoA concentrations are elevated, fatty acid synthesis is brisk, and the opposing pathway of fatty acid oxidation is blocked. Under these circumstances the physiologic role of malonyl CoA can be viewed as a mechanism to ensure unidirectional flow of carbon from glucose (or other precursors of pyruvate), into the sequence long-chain fatty acid $\rightarrow$ triglyceride $\rightarrow$ very low density lipoprotein through suppression of the activity of CPT I, thereby preventing the futile reoxidation of newly synthesized fatty acids. In the absence of food or in uncontrolled diabetes, insulin is deficient and glucagon concentrations are high. This results in a fall in malonyl CoA synthesis, with the consequence that lipogenesis slows and CPT I becomes activated. Fatty acid oxidation is further enhanced by the rise in tissue carnitine (mechanism not yet determined). Simultaneously, low plasma insulin levels allow activation of lipolysis such that ample free fatty acid substrate is now available to the derepressed hepatic ketogenic machinery. As fatty acyl CoA levels in the liver rise, backup inhibition of acetyl CoA carboxylase is assured. With carbohydrate feeding or the administration of insulin, the glucagon:insulin ratio falls and the entire sequence is ultimately reversed.

Increased oxidation of fatty acids in the liver, initiated by the fall in malonyl CoA concentrations, is the primary cause of all ketotic states. However, it should be emphasized that rates of ketone use in peripheral tissues are not unlimited. Once these processes are saturated, plasma ketone levels rise disproportionately to synthetic rates. Such saturation never occurs in the ketosis of fasting, but is characteristic of alcoholic and diabetic ketoacidosis.

Solution of the control of ketogenesis took several decades and the work of many investigators. It is quite remarkable that at the heart of the mystery was a simple molecule, malonyl CoA. It functions not only to regulate the opposing pathways of fatty acid synthesis and oxidation, but also represents a key link between carbohydrate and lipid metabolism in the liver. Evidence is accumulating that the malonyl CoA-CPT I interaction also plays a regulatory role in "fuel crosstalk" in a variety of nonhepatic tissues, in particular heart and skeletal muscle.^{38,39} The dominant form of CPT I expressed in myocytes is the so-called M (for muscle) variant, which is a separate gene product from the L (for liver) type enzyme.⁴⁰ Curiously, compared with L-CPT I, M-CPT I is about 100 times more sensitive to inhibition by malonyl CoA. It is of interest that both heart and skeletal muscle contain acetyl CoA carboxylase activity, and that in both sites the concentration of malonyl CoA changes reciprocally with the rate of fatty acid oxidation under different nu-

tritional and experimental conditions.³⁸⁻⁴⁰ Since neither tissue expresses significant levels of fatty acid synthase, it seems likely that the function of malonyl CoA in heart and skeletal muscle cells is solely for the regulation of fatty acid oxidation.^{38,39} Finally, the possibility has been raised that malonyl CoA inhibition of CPT I activity represents an important component of glucose-stimulated insulin secretion by the pancreatic β cell.^{41,42}

EPILOGUE

It is noteworthy that interest in the mitochondrial carnitine palmitoyl transferase enzyme system has suddenly begun to grow at an exponential rate. Several reasons for this renaissance can be discerned. First, as discussed previously, it is now clear that CPT I represents a pivotal site in the overall regulation of mammalian fatty acid metabolism. Second, there is growing momentum in the pharmaceutical industry to design drugs that will selectively suppress the activity of CPT I in liver and thus act as hypoglycemic agents.⁴³ Third, inherited defects in mitochondrial fatty acid transport, some with pathologic consequences, are now being documented more and more frequently.⁴⁴ Finally, and quite remarkably, this complex, membrane-bound dual enzyme system, known to be present in essentially all tissues of the body but discussed solely in operational terms for most of the past 30 years, has only recently proved amenable to analysis at the molecular level.⁴⁰ Although further discussion on this point is beyond the scope of the present review, exciting new insight into structure-function-regulatory relationships surrounding the CPT enzymes and the control of their respective genes can be expected in the near future.

FIGURE 2-4. Relationship between fatty acid synthesis and oxidation in liver. In the normal, fed state (high insulin:glucagon ratio) fatty acid synthesis from glucose is active, resulting in an elevated level of malonyl CoA. This causes suppression of CPT I activity such that newly formed fatty acyl CoA molecules are directed away from oxidation and into the esterification pathway leading to very low density lipoprotein (VLDL) production. Conversely, in starvation or uncontrolled diabetes (low insulin:glucagon ratio) fatty acid synthesis ceases because of inhibition of glycolysis and the acetyl CoA carboxylase (ACC) reaction. The concomitant fall in malonyl CoA concentration allows derepression of CPT I such that fatty acids mobilized from fat depots and entering the liver can readily react with carnitine and enter the β -oxidation pathway, allowing efficient production of ketone bodies. Note that pyruvate is a poor ketogenic substrate because its ability to generate acetyl CoA is low compared with that of fatty acids. For simplicity, CPT I has been placed outside the mitochondrion though it actually resides on the outer mitochondrial membrane.

The Molecular and Cell Biology of the Beta Cell

Kevin Docherty

Donald F. Steiner

INTRODUCTION

The discovery of insulin in 1921¹ ushered in the modern era of diabetes therapy and at the same time opened many new areas for biochemical and physiological investigation—activities that continue to flourish. Insulin is a small globular protein (MW ~5800 kD) consisting of two peptide chains, designated A and B, linked together by two disulfide bonds (Fig. 3-1).² It is produced and secreted by the β (beta) cells of the islets of Langerhans and acts by binding to a receptor molecule located on the plasma membrane of its target tissues. The receptor is a large integral membrane protein consisting of two polypeptide chains, the alpha and beta subunits, each present in two copies forming a heterotetramer ($\alpha_2\beta_2$). Although the molecular mechanism of signal transduction by the insulin receptor continues to be intensively investigated (see Chapt. 5), it is now clear that the receptor initiates a series of intracellular chemical events, including tyrosine phosphorylations on various targets, that lead to increased use and storage of glucose, as well as enhanced nitrogen retention and somatic growth (in immature organisms).

Both insulin and its receptor are derived from single-chain precursor molecules that are each encoded in a single autosomal gene. Biosynthesis results in the production of proinsulin, or proreceptor. These molecules are then processed posttranslationally to yield the mature proteins which are either stored for secretion, as in the case of insulin, or in the case of the receptor, transferred to the plasma membrane via small constitutive or unregulated vesicles. A great deal of information has accumulated in recent years on the structure and expression of the insulin gene. This chapter will describe the insulin gene, the molecular mechanisms underlying the biosynthesis and conversion of proinsulin, and the regulation of these processes by glucose and other factors. The clinical relevance of proinsulin and C peptide will be reviewed, and islet amyloid peptide (IAPP) or amylin, a newly identified neuropeptide product of the β cell that is cosecreted with insulin and is a major constituent of islet amyloid deposits in type 2 diabetes mellitus (T2DM), will be discussed.

INSULIN STRUCTURE

Insulin occurs in all vertebrates (Fig. 3-1), and two-chain insulin-like substances have been found in the nervous or digestive systems of several invertebrates.³ These include a growth-promoting hormone of the light green cells in the snail *Lymnaea*,⁴ an insulin-

like brain peptide from the silkworm *Bombyx mori*,⁵ an insulin-like peptide from the locust,⁶ and the recently discovered multi-insulin-related genes in *Caenorhabditis elegans*.⁷ Vertebrates have insulin-like growth factors (IGF-I and -II), single-chain peptides related to proinsulin, which interact with growth hormone, insulin, and other hormones to regulate both somatic and tissue growth. These forms are found only in vertebrates and are believed to have arisen via gene duplication from the insulin gene early in vertebrate evolution.⁸ Many tissues express a receptor—the IGF receptor—that is closely similar in structure to the classic insulin receptors, but which preferentially binds IGF-I and also IGF-II. A separate IGF-II binding receptor that also binds mannose-6-phosphate and has tyrosine kinase activity and appears to serve as an IGF scavenger. Other less closely related members of the insulin superfamily include ovarian relaxin¹⁰ and several recently discovered relaxin-like hormones.^{11,12}

Certain structural features of insulin have been highly conserved throughout vertebrate evolution, including the positions of the two disulfide bonds, the N-terminal and C-terminal regions of the chain, and the hydrophobic residues in the C-terminal region of the chain (see Fig. 3-1). These residues influence receptor binding and are also intimately associated with maintaining the native three-dimensional structure of the hormone, as revealed by the x-ray crystallographic studies of Baker and coworkers.¹³ The structure of the porcine insulin monomer is shown in Fig. 3-2. In this high-resolution (0.15-nm) representation, all the amino acid side chains are shown in their normal orientations and the putative receptor binding region is outlined. Nuclear magnetic resonance (NMR) studies¹⁴ provide support for the conclusion that the structure of the insulin monomer in solution is closely similar to that in the crystals. Human and most other mammalian insulins form hexamers in the presence of zinc, and it is this form that exists in the rhombohedral Zn-insulin crystals.

Other recent studies have led to new insights regarding the location of the receptor binding region(s) in the insulin molecule, especially studies with several naturally occurring human insulin mutants involving residues A3, B24, and B25¹⁵ and with desproteins of insulin, in which the last five residues of the B chain have been deleted,¹⁶ as well as with certain insulins with crosslinks between B29 and A1.¹⁷ These data suggest that during receptor binding, the flexible C-terminal region of the B chain is reoriented, exposing underlying residues, such as A3 valine. Recent NMR data on various insulin derivatives in solution^{14,18,19} also confirm the importance of significant conformational changes in the C terminus.

of the B chain in receptor binding. A question that remains unanswered is whether the insulin molecule interacts with more than one site on the receptor molecule in order to achieve the typical high affinity binding isotherm and curvilinear Scatchard.²⁰

BIOSYNTHESIS OF INSULIN

The precursor of insulin is preproinsulin (Fig. 3-3), which consists of a single chain of 110 amino acids having a hydrophobic

FIGURE 3-2. View of a monomer of porcine insulin. The side chains of all the amino acids are shown: the A chain is dark gray and the B chain is light gray. The dashed outline delineates the approximate region on the surface of the insulin monomer which is believed to contact the receptor upon binding. (Computer graphic representation kindly provided by Dr. Bing Xiao, University of York.)

24-amino-acid N-terminal prepeptide or signal peptide in most mammalian species.^{21,22} The signal peptide facilitates the transfer of proinsulin from the cytosolic compartment, where protein chain elongation occurs, into the secretory pathway. Interactions involving signal recognition particle (SRP) and the SRP receptor in the membrane of the rough endoplasmic reticulum (RER) lead to the translocation of the nascent peptide into its internal compartments, or cisternae.^{23,24} During translocation the signal sequence is rapidly removed by the signal peptidase, a protease located on the inner surface of the RER membrane,²⁴ to give rise to proinsulin, which then folds and undergoes rapid formation of disulfide bonds, catalyzed by the enzyme protein-thiol reductase, to gain its native structure. Proinsulin is a stable precursor that includes the insulin B and A chains within a single 9000-kd polypeptide chain.²⁵⁻²⁷ Newly formed proinsulin is then transported to the *cis* region of the Golgi apparatus for further processing and packaging (Fig. 3-4), while the signal peptide is rapidly degraded in the RER and is not a secretory product.

During the intracellular maturation of secretory granules, proinsulin is cleaved to yield insulin and a 31-residue (in humans and several other mammals) connecting peptide fragment designated the C peptide. Both insulin and C peptide are stored in mature secretion granules along with small amounts of residual proinsulin and its intermediate cleavage forms²⁸ as well as various other minor secretory products.²⁹ Due to the time required for transit from the RER to the immature granules, conversion of proinsulin to insulin begins only about 20 minutes after peptide chain synthesis is completed, and it then proceeds as a pseudo first-order process with a half time of 30–60 minutes. It requires neither energy nor continued protein synthesis once initiated in the granules. Mature β -cell secretory granules contain only low percentages (1–2%) of proinsulin and intermediate materials, and as a consequence, secreted insulin normally contains only small amounts of these precursor-related peptides.³⁰ Newly synthesized insulin and proinsulin are selectively released to a slight extent, but the bulk of the secreted material normally consists of stored preformed hormone and C peptide.³⁰⁻³²

Numerous studies have confirmed that like other cells that elaborate secretory proteins, newly synthesized proinsulin passes via the Golgi apparatus into the β -cell secretory granules (Fig. 3-4). Immunocytochemical studies using monoclonal antibodies specific for uncleaved proinsulin have demonstrated that newly formed clathrin-clad granules in the *trans* Golgi cisternae

FIGURE 3-3. Schematic structure of human preproinsulin. Removal of the first 24 amino acids (signal peptide) gives rise to proinsulin. Cleavage after B30 (T) and before A1 (G) gives rise to insulin and C peptide.

are rich in proinsulin, confirming that conversion to insulin occurs principally during the maturation of these secretory “progranules.”^{33,34} Energy is required for the intracellular translocation of secretory proteins from RER through the Golgi apparatus, and is associated with the budding and/or fusion of small non-clathrin clad vesicles that transport secretory proteins from the *cis* through the *trans* Golgi cisternae.^{35,36} Because proteolytic conversion itself does not require energy, it is likely that proinsulin processing is initiated in the *trans* compartment of the Golgi apparatus or in newly formed secretory granules, or progranules, as these leave the Golgi region, and that it continues for several hours within these granules as they collect and mature biochemically in the cytosol (Fig. 3-4).

The major proteolytic cleavages required for converting proinsulin to insulin are summarized in Fig. 3-5. In early studies it was shown that the conjoint action of trypsin and carboxypeptidase B can give rise to the naturally occurring pancreatic products C peptide and native insulin, essentially quantitatively converting proinsulin to insulin *in vitro*,³⁷ a process used in some commercial processes for making recombinant human insulin via proinsulin.³⁸

The Prohormone Convertases and Proinsulin Processing

The identification of the proinsulin convertases has led to the solution of the longstanding puzzle as to the nature of the endoproteases responsible for the cleavage of prohormones characteristi-

cally at paired basic residues. Two novel calcium-dependent endoproteases (PC2 and PC3/PC1) related to subtilisin, a bacterial serine protease, and to kexin, a yeast-mating pheromone convertase, were found by polymerase chain reaction strategies applied to human insulinoma cDNA and to AtT20 cells.^{39,40} PC3/PC1 was present at lower levels in the human insulinoma but at higher levels in ACTH-secreting AtT20 cells. PC2 consists of 638 residues, and PC3/PC1 contains 753 residues. Their structures are shown diagrammatically in Fig. 3-6.

A related human protease, furin, that was identified serendipitously, was initially believed to be a growth factor receptor due to the presence of a cysteine-rich domain and a putative transmembrane segment.^{41,42} However, this protease also contains a catalytic domain similar to that of PC3/PC1, PC2, and kexin, having the characteristic catalytic Ser-Asp-His triad of active site residues (Fig. 3-5). Subsequent studies have shown that furin, like yeast kexin, is localized to the *trans* Golgi region, and that it is expressed ubiquitously in tissues, where it serves to process a variety of precursors secreted via constitutive pathways, such as insulin receptor precursors and other growth factors, clotting factor precursors, and viral envelope glycoproteins.⁴³

PC2 and PC3 lack transmembrane localization domains and are optimally active at pH 5.5.⁴⁴ They are expressed (in varying amounts) only in neuroendocrine tissues such as the islets of Langerhans, pituitary, adrenal medulla, and many regions of the brain, but not at appreciable levels in other nonendocrine tissues such as liver, spleen, intestine, kidney, or muscle.^{40,45} Moreover, antisera to PC2 and PC3 indicate that the β cells, as well as other cell types of the islets of Langerhans, express one or both

FIGURE 3-4. Schematic model of the insulin biosynthetic machinery of the β cell. Preproinsulin is synthesized in the rough endoplasmic reticulum (RER) and is then rapidly cleaved to proinsulin (within 1–2 minutes). In the intracisternal spaces of the RER, proinsulin folds and forms the native disulfide bonds of insulin. After being transported to the Golgi apparatus by an energy-requiring vesicular mechanism, proinsulin is efficiently sorted (>99%) into clathrin-coated early granules arising in the *trans* Golgi network. These granules are rich in proinsulin and contain the converting proteases, PC2 and PC3, and carboxypeptidase E. Processing to proinsulin occurs mainly, if not exclusively, in these early secretory granules, giving rise to the more condensed mature granules, which lack the clathrin coat. The mature granule-dense cores consist almost entirely of insulin, often in crystalline arrays, while the granule-soluble phase that surrounds the inclusion consists mainly of C peptide and small amounts of proinsulin. The release of newly synthesized proinsulin and insulin begins about 1 hour after synthesis in the RER, and hence granules must undergo a maturation process that renders them competent for secretion. Nongranular routes of secretion of proinsulin or insulin comprise only a few percent of total secretion in normal islets. Exocytosis of granules is regulated by glucose and many other factors, and in both humans and dogs results in the release of insulin and C peptide in equimolar proportions under both basal and stimulated conditions.

these proteases. Immunogold labeling of both proinsulin and PC2 in newly formed β -cell secretory vesicles has confirmed the colocalization of the enzyme and its putative substrate.⁴⁶

Various studies indicate that PC2 cleaves proinsulin preferentially at the Lys Arg ↓ Gly sequence at the junction of the C peptide and the A chain, and PC3 cleaves mainly at the Arg Arg ↓ Glu sequence in the B chain-C peptide junction.⁴⁶ These and other findings support the proposed identity of PC3 and PC2 with the calcium-dependent type 1 and type 2 insulinoma granule proinsulin processing activities, respectively, described by Davidson, Bailles, and Bennett and all their coworkers.^{47–49} Sizonenko and Halban⁵⁰ have reported that rat/mouse proinsulin II, which has Met

rather than Lys at B29, four residues upstream (P4 position) of the B chain-C peptide cleavage site, is processed more slowly at this site in normal islets. These results and others suggest that both PC3 and PC2 cleavage, like that of furin, is augmented by basic residues at the fourth position upstream from the cleavage site (designated P4) in some of its substrates, and this could account for observed cleavage of rat/mouse proinsulins at the A-chain junction (Arg Gln Lys Arg ↓ Gly) by PC3 in early studies.⁴⁶

More recent studies confirm that both PC2 and PC3 participate in the processing of proinsulin and indicate that their action is most likely sequential, with PC3 acting initially to produce 32,33 split proinsulin, which is a preferred substrate for PC2 cleavage at the remaining C peptide-A chain junction. This is illustrated schematically in Fig. 3-5. Recent studies of insulin biosynthesis in islets from a PC2 null mouse strain⁵¹ have confirmed the importance of PC2 for proinsulin processing.⁵² The pancreatic proinsulin content in these mice is significantly elevated (~35% vs. ~5% in wild-type or heterozygotes) and circulating levels of proinsulin approach 60%. Pulse-chase labeling studies show that the rates of proinsulin processing are reduced by about threefold and significant accumulations of des 31,32 proinsulin intermediate, resulting from PC3 action, are evident.⁵² In normal human islets of Langerhans, significant levels of des 31,32 proinsulin accumulate during pulse-chase studies.⁵³ This occurs because human proinsulin lacks a P4 basic amino acid at the C peptide-A chain junction, which slows PC2 cleavage at this site, while the B chain-C peptide site has a lysine as the P4 residue. As a consequence of this simple structural difference, in humans the des 31,32 intermediate form makes up a considerable proportion of normal circulating insulin-like components, in addition to intact proinsulin.^{52–54}

PC2 has also been shown to be expressed at high levels in the α cells, where it appears to act alone in the processing of proglucagon to release only glucagon as the major hormonal product.^{55,56} Glucagon-like peptide 1 (GLP-1_[7–37]), another endocrine product derived from proglucagon by selective proteolysis in the intestinal L cells, has been shown to be an important incretin, augmenting insulin secretion in response to ingested fuels, and opposite to glucagon, which is an insulin counterregulatory hormone. (see chapt. 6 and 7) The L-cell processing enzyme has been tentatively identified as PC3, since PC3 has been shown to carry out the cleavages leading to the release of GLP-1 and GLP-2, but not of glucagon from proglucagon.^{57,58} In the PC2 null mice proglucagon processing is markedly impaired, leading to a lack of circulating mature glucagon and resulting in chronic hypoglycemia and α cell hyperplasia.⁵¹ PC2 is also the major convertase expressed in the islet somatostatin-producing delta cells, and consequently processing of prosomatostatin to somatostatin 14 is blocked. Instead, somatostatin 28 accumulates in the PC2 nulls. The pancreatic polypeptide (PP)-producing gamma cells also are rich in PC2, and so the processing of proPP may also be impaired. All of these results and others indicate that PC2 and PC3 are major secretory granule-processing enzymes and are responsible for processing many neuroendocrine precursors.^{46,59} For further information on the prohormone convertase family of processing enzymes, see references 60–63.

Another important component of the processing machinery, carboxypeptidase E (CPE), a carboxypeptidase B-like enzyme, was first identified in islets but is expressed in many other neuroendocrine tissues, including brain (Fig. 3-5). This enzyme has been

FIGURE 3-5. The cleavage of proinsulin to insulin by the combined action of the prohormone convertases PC2, PC3/PC1, and carboxypeptidase H. This scheme is based on evidence, cited in the text, that PC3 cleavage at the B chain-C peptide junction precedes cleavage by PC2 at the C peptide-A chain junction. The conformation shown for proinsulin is based on modeling studies to optimize binding to the convertases during cleavage.²⁸⁴ Note that the interaction with PC2 requires unwinding of the N-terminal alpha helix of the A chain to allow the A2 Ile residue to move out from the hydrophobic core of the insulin moiety, where it normally resides with the A19 Tyr, to enter the active site of PC2 (subsite S2').

extensively studied both in terms of its enzymatic properties as well as its biosynthesis.⁶⁴ These studies have shown that it is clearly distinct from the classical pancreatic carboxypeptidases A and B, but is structurally homologous to these enzymes, suggesting that it arose from a common ancestral exopeptidase.⁶⁴ The CPE^{fat} mutation is a spontaneously occurring loss of function mutation in

CPE that causes a metabolic syndrome characterized by obesity, mild diabetes, and hyperproinsulinemia.⁶⁵ CPE activity is absent in the islets and reduced⁶⁶ in brains of these mice. Interesting absence of CPE leads to impaired convertase action, perhaps in part to the accumulation of cleaved intermediates extending C-terminally with basic residues.⁶⁷

FIGURE 3-6. Schematic structures of the proinsulin processing prohormone convertases PC2 and PC3/PC1. The various subregions are designated as follows: signal peptides (SP), proregion (PRO), catalytic domain (CAT), P or homeo B domain (P), and amphipathic helix (AH). The catalytic Asp, His, Asn (Asp), and Ser residues, cleavage sites (?) and a potential integrin-binding sequence (RGD) are shown. C-terminal shortening of PC2 occurs in the secretory granules.

Secretory Granule Formation

In β cells the "progranules" characteristically are less dense than the mature granules and have a uniform density throughout.^{33,68} Evidence suggests that newly synthesized proinsulin enters these granules as a sol rather than an aggregate. Various changes take place as these progranules mature in the cytoplasm of the cell, including the proteolytic conversion of proinsulin to insulin and the condensation of the insulin with Ca and Zn ions.^{69,70} The dense central core of mature insulin-secretory granules is crystalline with repeat-unit spacings closely similar to those of ordinary zinc insulin crystals.^{71,72} Thus as insulin is liberated from proinsulin, it tends to crystallize with zinc that is concentrated by the β cells. The role of zinc in secretory granule formation is not well understood.⁷³ Most of the zinc in islets is present in the β granules and is liberated proportionately with insulin during secretion.⁷⁴ Mature islet secretory granule cores seem to contain only insulin, while the C-peptide liberated in the conversion process remains in solution in the clear fluid space surrounding the dense crystalline core.⁷² The C peptide does not cocrystallize with insulin, but low levels of proinsulin do cocrystallize with insulin such that granule cores normally contain 1–2% of intact or partially processed precursor,⁷² mainly des 31,32 intermediate in man.⁵⁴

The pH of the interior of the mature secretory granule is approximately 5.0,^{33,34} an optimal pH for both proinsulin conversion and insulin crystallization. In contrast, the *trans* Golgi and newly formed secretory granules are more nearly neutral, which may favor receptor-mediated sorting mechanisms, such as those involved in the sorting of lysosomal enzymes into endosomes via mannose-6-P receptors. Thus the biosynthesis of insulin via preproinsulin and proinsulin and their intracellular handling, proteolysis, and ultimate storage as insulin in secretory granules, is a remarkably well-integrated process, at both the molecular and cell biological levels, within the β cells.^{74,75} This well-poised mechanism is disturbed in islet cell tumors, which often show unregulated release of insulin and other hormones together with excessive amounts of proinsulin. Measurements of proinsulin levels are thus useful adjuncts in the diagnosis of islet cell tumors (see Chap. 58).^{76,77}

C Peptide as a Product of Proinsulin Transformation

C peptide accumulates along with insulin in essentially equimolar amounts^{28,78} and is secreted along with the hormone by exocytosis of the granule contents.^{75,78} Recent studies suggest that a small proportion (2–3%) of newly synthesized C peptide may be released constitutively,⁷⁹ presumably due to budding of small clathrin-coated vesicles from newly formed secretory granules. Because mammalian C peptides exhibit a 15-fold higher rate of mutation acceptance than the corresponding insulins, it seems likely that this region in the proinsulin molecule does not have any specific hormonal function. Nonetheless, it has been suggested that low-dose (biosynthetic) C peptide infusion may influence human muscle microcirculation as well as renal function by unknown mechanisms.⁸⁰

The renewal and regulation of the granular stores of insulin and C peptide in the β cells is an important aspect of normal homeostasis. Calcium-dependent exocytosis of preformed storage granules⁸¹ appears to be the major source of both basal and glucose-

stimulated insulin and C peptide release *in vivo*.⁷⁵ The chief positive effector in maintaining this storage compartment is glucose, augmented by cyclic AMP, which appears to be generated by a mechanism closely coupled to glucose metabolism in the β cell.^{82–84} Secretion is not a direct stimulus to insulin biosynthesis, as can be proven by blocking secretion by lowering external calcium levels or using inhibitors such as diazoxide. These agents do not impair the biosynthetic response to glucose.²⁸ However, when inhibition of secretion is prolonged, intracellular degradation (autophagy) of granules occurs.^{34,75}

Clinical Relevance of Proinsulin and C Peptide

The measurement of the secretion rate of insulin *in vivo* is complicated by its rapid plasma half-life, which is in turn determined in part by the pool of available insulin receptors in the liver and peripheral tissues. A large proportion of normal insulin metabolism, beyond renal disposal, appears to result from receptor-mediated endocytosis, followed by intracellular degradation of the hormone in liver and other target tissues, perhaps as modulated by still other factors such as hepatic glucose metabolism.⁸⁵ As a consequence the relationship between circulating insulin levels and the rates of secretion of the hormone from the pancreas is complex and difficult to assess. It is further complicated in the insulin-treated diabetic by the presence of insulin antibodies and pools of residual bound and free hormone, even after withdrawal of insulin therapy.

The C peptide, on the other hand, represents a cosecreted product that is directly related stoichiometrically to insulin on a one-to-one basis and is far less complicated to measure. It is not extracted significantly by the liver, and its metabolic clearance rate is independent of its plasma concentration over a wide concentration range. Whether a receptor exists for C peptide is an unsettled topic, but its prolonged half-life and kinetically accessible distribution characteristics suggest that it is probably biologically inert and is mainly excreted by the kidney. No effects of metabolic state have been observed on C-peptide distribution or turnover. By a deconvolutional analysis that corrects for distribution beyond plasma compartments, Polonsky and coworkers have shown that peripheral C-peptide levels can be used to derive true secretion rates for insulin *in vivo* under a variety of conditions, including the presence of insulin antibodies.⁸⁵

C-peptide measurement has proven helpful in the diagnosis of hypoglycemia due to insulinoma and/or surreptitious administration of insulin. In the former case, failure to suppress C-peptide levels during insulin-induced hypoglycemia (levels below 50% of baseline when blood glucose falls below 40 mg/dL) strongly suggests insulinoma. In contrast, factitious insulin administration should be suspected when very high insulin concentrations are accompanied by normal or suppressed C-peptide levels.

Proinsulin is normally secreted in much smaller amounts than insulin or C peptide (usually 3–5%). However, its rate of metabolism is much slower than that of insulin because of its reduced insulin receptor affinity (approximately 3% that of insulin). But some proinsulin intermediates, particularly des 64,65 proinsulin (cleaved at the C peptide-A chain junction), exhibit potencies approaching that of insulin and hence are more rapidly metabolized. Whether for this reason or others, several recent studies have determined that circulating proinsulin-like material (PLM) is mainly composed of intact proinsulin and des 31,32 proinsulin (cleaved at the B chain-C peptide junction), both being low-potency, slow-

turnover forms. These forms make up a small proportion (10–20%) of normal fasting plasma but may account for as much as 50% of circulating insulin components in type 2 diabetes.⁸⁶ This finding has led to suggestions that conversion of proinsulin to insulin may be impaired in the diabetic β cell and high proinsulin levels may tend to obscure the extent of bioactive insulin deficiency, based on simple plasma insulin radioimmunoassays (which fail to distinguish between active insulin and these less active biosynthetic intermediates). Whether this circulating imbalance may also be due in part to more rapid insulin disposal in the diabetic (due to receptor upregulation) remains an issue that requires further clarification. Nonetheless, there appears to be some basis for believing that elevated secretion of proinsulin-related materials may be a concomitant of β -cell decompensation, although the mechanistic basis for this phenomenon is not well understood (see Chap. 21). Recent studies of the effects of prolonged exposure of β cells to elevated fatty acids on insulin biosynthesis indicate inhibition of maturation of not only proinsulin, but also of the convertases, resulting in secretion of increased proportions of proinsulin.⁸⁷

Proinsulin is stable in the circulation and is cleared mainly by the kidney. Hence renal failure is usually accompanied by markedly elevated proinsulin levels. Elevated proinsulin is frequently found in patients with insulinomas. More than 80% of benign adenomas and almost all islet cell carcinomas manifest elevated proinsulin levels that are not suppressed by hypoglycemia.⁷⁶ Biosynthetic human proinsulin has been tested in clinical trials as a potential long-acting form of insulin. These studies unfortunately revealed a slight excess of cardiac mortality in the proinsulin group and were discontinued.³⁸ Whether lower, more physiologic proportions of proinsulin in combination with insulin (and C peptide) might have superior therapeutic characteristics than insulin alone remains a possibility deserving further exploration. Recent studies suggest the existence of high-affinity proinsulin-specific receptors on vascular endothelial⁸⁸ and intestinal crypt⁸⁹ cells.

STRUCTURE AND EVOLUTION OF THE INSULIN GENE

The gene for insulin was among the first to be isolated. Its structure in man⁹⁰ is summarized in Fig. 3-7. The insulin gene has been cloned from a wide range of species including primates, rodents, birds, fish, and amphibians.^{91,92} Its structure is highly conserved among species and consists of three exons and two introns. Exon 1 is located in the 5' untranslated region of the gene. Exon 2 contains sequences encoding the signal peptide, the insulin B chain and part of the C peptide, while exon 3 encodes the remainder of the C peptide, the insulin A chain and the 3' untranslated sequences.⁹⁰ The length and sequence of the introns are highly variable among species. However, the relative length of intron 1 is always less than that of intron 2, and it is located in the 5' untranslated region while intron 2 interrupts the gene between the first and second nucleotides of the codon for amino acid 7 of the C peptide.

Only one insulin gene is present in most species studied, with the exception of rat, mouse, and *Xenopus*, which have two nonallelic insulin genes. Intron 2 is absent from the rat and mouse insulin I genes. The second gene of rodents (i.e., rat and mouse insulin I) arose from a process of reverse transcription of a partially spliced germ line transcript.⁹³ The RNA transcript involved was

initiated from a site upstream of the normal physiological promoter of the insulin II gene; thus the insulin I gene is homologous to the insulin II gene within about 500 bp upstream of the transcription start site. The rat and mouse insulin I and II genes are expressed equally in normal islets,⁹⁴ though not in fetal yolk sac or in some rat insulinoma-derived cells.⁹⁶ Both alleles of mouse insulin I and II genes are active in embryonic tissue but only the paternal alleles for both genes are active in the yolk sac.⁹⁷ This suggests that the maternal alleles undergo selective imprinting in extrapancreatic tissue during embryonic development, raising questions about the role of such extrapancreatic expression.

The single-copy human gene is located on the short arm of chromosome 11 in band p15.^{98,99} It is flanked on the 5' side by a unique polymorphic region composed of tandem repeats that extend beyond the upstream regulatory region and does not seem to influence its expression but provides a useful marker for genetic linkage analysis.¹⁰⁰ Earlier reported correlations of the presence of large (Class 3) versus smaller (Class 1 or Class 2) repeats in this region with the incidence of type 2 diabetes were confounded by ethnic differences in the distribution of tandem repeats. Further analysis of larger populations failed to support this conclusion, but have revealed that Class 1 alleles and genotypes are significantly more frequent in Caucasians with type 1 diabetes than type 2 diabetic controls.¹⁰¹ This allele may thus be a marker for a nearby susceptibility gene for type 1 diabetes mellitus (T1DM).

REGULATION OF INSULIN GENE TRANSCRIPTION

DNA Sequences and Transcription Factors Controlling Transcription of the Insulin Gene

β -cell-specific expression of the insulin gene is dependent on DNA sequences located within a region of approximately 400 base pairs immediately upstream of the transcription start site.^{102–106} This region is highly conserved among species and contains a number of regulatory elements as depicted in Fig. 3-8.¹⁰⁷ The transcription factors that bind to these promoter elements play an important role in (1) restricting expression of the insulin gene to β cells, (2) silencing the insulin gene in non β cells, (3) determining when and where the insulin gene is expressed during islet cell ontogeny, and (4) regulating expression of the insulin gene in response to changes in nutrient status. Transcription factors, some of which bind to the insulin promoter, also play an important role in lineage determination in the developing pancreas while defects in these transcription factors may be related to the development of diabetes mellitus.

Of the regulatory sequences depicted in Fig. 3-8, the two E-box elements GCCATCTGC (E1 and E2) are particularly important. Transcription factors that bind E boxes consist of heterodimers between a ubiquitous class A and a tissue-specific class B member of the basic helix loop helix (bHLH) family. These proteins contain a conserved basic DNA-binding domain and two amphipathic helices separated by a loop structure that are required for dimerization. Class A bHLH members include the E2A gene products E12 and E47, while class B family members include BETA2/NeuroD, MyoD, and myogenin. Other class B proteins such as Id, emc, and hairy, which lack a basic DNA-binding domain, can form inactive heterodimers with class A proteins.

FIGURE 3-7. Diagrammatic representation of the structure of the insulin gene in vertebrates. Exons (E) appearing in mature preproinsulin mRNA are shown as bars and the sizes of the two introns or intervening sequences (I) in various species are tabulated below. U, Untranslated region; P, prepeptide coding region; B, B-chain coding region; C, C-peptide coding region; and A, A-chain coding region. A typical TATA box signaling transcription initiation is shown approximately 30 base pairs upstream from the messenger start site, preceded by a promoter region (unfilled box). The human insulin gene, abbreviated INS, is located on the short arm of chromosome 11 in the region p15.^{98,99}

The E1 element located at approximately -100 is highly conserved among insulin genes. It is critical for insulin gene expression, since mutagenesis has a drastic effect on insulin promoter activity.¹⁰⁸ The E1 element binds a heterodimer of the ubiquitously expressed E2A gene product E47 and BETA2, which is also known as NeuroD.^{109,110} BETA2/NeuroD is expressed in islets of Langerhans, brain, and intestine (where it is thought to regulate the secretin gene).¹⁰⁹ The importance of BETA2/NeuroD is emphasized by inactivation of the gene in mice: mice homozygous for the *BETA2/NeuroD* gene deletion develop severe diabetes and die 3–5 days after birth.¹¹¹ On the other hand, mice lacking the *E2A* gene exhibit normal levels of insulin, suggesting functional redundancy among members of the class A bHLH family.¹¹²

The E2 region, located at around -230, is not as well conserved as the E1 region. In the rat insulin I gene the sequence of the E2 box is identical to that of the E1 box, and it binds a similar factor, i.e., E47/BETA2. The E2 box of the human insulin gene differs from the E1 box. It has an imperfect E box, CACCGG, which binds E47/BETA2 but only weakly. However, it binds the ubiquitously expressed bHLH factor USF (upstream stimulating factor) with high affinity.¹¹³ On the 5' side of the E2 box is an element (C2) containing a number of CAGG sequences. This C2 element binds

an islet cell-specific factor RIPE3b1,¹¹⁴ which was originally shown to bind to the C1 element located between the A1 and E1 boxes of the rat insulin II gene.¹¹⁵ RIPE3b1 has yet to be cloned and characterized.

The A box elements have the consensus sequence C(C/T)TAATG. There are four in the human insulin gene at positions -82 (A1), -140 (A2), -215 (A3) and -319 (A5). The A box binds a transcription factor PDX1, which was previously known as IPF1,¹¹⁶ IDX1,¹¹⁷ STF1,¹¹⁸ and IUF1.¹¹⁹ Expression of PDX1 in the adult is restricted to β cells of the pancreas and to somatostatin-expressing cells of the pancreas and small intestine. PDX1 belongs to the *Antennapedia* class of homeodomain proteins and is highly homologous to the *XlHbox 8* from *Xenopus laevis*.¹²⁰ Mice homozygous for a targeted mutation in the *pdx1* gene selectively lack a pancreas.¹²¹ These and other findings suggest that PDX1 functions both in the early specification of the primitive gut to a pancreatic fate and in the maturation of the pancreatic β cell.^{122,123} The human *pdx1* gene, located on chromosome 13q12, encodes a 283-amino-acid protein with a central homeodomain flanked by two proline-rich domains.¹²⁴ The transactivation domain is located at the NH₂-terminus of the protein.^{125,126} The mechanisms whereby PDX1 binding to the A box activates the

FIGURE 3-8. Schematic depicting the arrangement of regulatory sequences in the human insulin gene promoter. The scale at the bottom represents base pairs upstream of the transcription start site. The boxes on the dark line denote sequence elements, and when the name of the element and sequence are known, they are given. Above the boxes the transcription factors are schematically represented. The factor IEF1 is a heterodimer of BETA2/E47.

insulin gene is not well understood. It synergizes with bHLH proteins bound to the E1 element and with the homeodomain factor Pbx.^{127,128} The interaction with Pbx involves a conserved pentapeptide sequence, FPWMK, located amino terminal to the homeodomain. Some preliminary data on the sequences regulating the PDX1 gene have been published. A regulatory sequence that binds HNF3 β has been mapped to a DNase hypersensitive regions at about -2 kb,¹²⁹ while the bHLH protein USF binds to a regulatory site close to the promoter, at -104 .¹³⁰

Other putative regulatory elements that are conserved among species include a cyclic AMP-responsive element (CRE) and an enhancer core sequence that could bind C/EBP. In the rat insulin I gene a G-rich sequence binds a factor, Pur-1, that is ubiquitously expressed.¹³¹ A STAT5 binding site that may mediate the effects of growth hormone has been mapped to the sequence between -330 and -322 in the rat insulin I gene.¹³² And a complex negative regulatory element has been identified between -258 and -279 of the human insulin gene.¹³³ This element binds a number of proteins¹³⁴ and contains a palindromic repeat sequence that may function as a negative glucocorticoid response element.¹³⁵

The human insulin gene contains variable numbers of tandem repeats (VNTRs) of the sequence 5' TCTGGGAGAGGG 3' located upstream of -365 .¹⁰⁰ Termed the insulin-linked polymorphic region (ILPR), this region has been shown to exhibit transcriptional activity,¹³⁶ possibly through the binding of the transcription factor Pur-1 to G-rich sequences.¹³⁷ Interestingly, the ILPR has the ability to adopt an altered DNA structure. This has been characterized as a quadruplex involving interactions between the G residues on the top strand,^{138–140} while the C-rich strand forms hairpin structures.¹⁴¹ The quadruplex structure is present *in vivo*¹⁴² and in DNA assembled in chromosomes *in vitro*.¹⁴³ The structure is present when the insulin gene is actively transcribed, while mutations that destabilize the structure lower the transcriptional activity of the gene. Further regulatory sequences, including a steroid-responsive element¹⁴⁴ and a RIPE3b1 binding site,¹⁴⁵ may reside upstream of the ILPR.

Nutrient and Hormonal Control of Insulin Gene Expression

The biosynthesis and secretion of insulin by pancreatic β cells is controlled primarily by the circulating glucose levels. Metabolism of glucose is essential for its stimulatory effect as only metabolizable analogues are effective. Hexose phosphorylation in β cells by a high- K_m glucokinase is the rate-limiting step for sugar metabolism. Glucokinase is thus regarded as the β cell glucose sensor conferring concentration dependence and specificity to the insulin secretory response to sugars.¹⁴⁶ Metabolism of glucose results in an increase in the intracellular ATP/ADP ratio, which causes closure of the ATP-sensitive K^+ channel in the plasma membrane. The consequent depolarization causes opening of the voltage-dependent Ca^{2+} channel, and the increase in intracellular Ca^{2+} initiates the events that lead to exocytosis of the insulin granule contents (see Chap. 4). Hormones such as glucagon-like peptide I (7-37) (GLP-I) that activate adenylate cyclase stimulate insulin secretion by amplifying the response to glucose, primarily by increasing the sensitivity of the secretory apparatus to Ca^{2+} .¹⁴⁷ Insulin has also been shown to activate insulin secretion by an autocrine mechanism involving an increase in $[Ca^{2+}]_i$ and activation of protein kinase C.¹⁴⁸

Glucose can also stimulate insulin secretion in a K_{ATP} -channel independent manner. Thus, in the presence of diazoxide that inhibits the closure of K_{ATP} channels by glucose, the plasma membrane potential ($\Delta\psi$) is depolarized by K^+ , causing an increase in cytosolic Ca^{2+} to permissive levels.¹⁴⁹ It is thought that at this permissive level of Ca^{2+} , glucose can stimulate the activity of Ca^{2+} -sensitive dehydrogenases in the mitochondrial matrix. The resultant increased flow through the TCA cycle generates a mitochondrial factor distinct from ATP. This factor has been identified as glutamate, which leaves the mitochondria and interacts directly with insulin secretory granules to promote exocytosis.^{150,151}

Following the release of insulin it is important that the β cell replenishes its stores. There are several stages at which this can occur: transcription of the insulin gene, preRNA processing, transport into the cytoplasm and turnover of mRNA, and translation of preproinsulin mRNA.¹⁵² The major acute (<2 hours) control of insulin production is exerted at the level of translation. This is in keeping with the requirement to replenish insulin stores rapidly following insulin secretion in response to elevated circulating glucose levels. Over longer periods (>6 hours) glucose stimulates transcription of the insulin gene, and, at least in the mouse, it also regulates the level of preRNA splicing.¹⁵³

In recent years it has become clear that the cells within islets communicate with each other through connexin-like molecules, such that the overall response to nutrient stimulation reflects the integrated action of β cells with individually differing behaviours.¹⁵⁴ Thus an increase in glucose concentrations not only stimulates gene expression and proinsulin biosynthesis within individual β cells, but also increases the number of cells that respond to glucose.¹⁵⁵ The following account of events should therefore be viewed in the context of this synergistic response.

Evidence that glucose affects insulin mRNA levels initially came from *in vivo* experiments in which rats fasted for 4 days exhibited decreased insulin mRNA levels which could be restored to normal on refeeding or injection of glucose.¹⁵⁶ *In vitro* studies¹⁵⁷ confirmed that this occurred through stabilization of insulin mRNA and through effects on the rate of transcription of the insulin gene.¹⁵⁸ Insulin mRNA is relatively stable, with a half-life of about 30 hours; however, its half-life was almost threefold longer in islets incubated in 17 mmol glucose compared with 3 mmol glucose.¹⁵⁹ Direct effects of glucose on gene transcription were demonstrated by using transcription run-on assays or transfection of plasmid constructs containing insulin promoter fragments joined to a reporter gene encoding chloramphenicol acetyl transferase (CAT) or firefly luciferase.^{160–162}

A glucose-responsive element was originally mapped to the E2/A4/A3 (-196 to -247) region of the rat insulin I gene promoter in transfected neonatal rat islets.¹⁶¹ Part of this response results from the binding at the E2 site of a protein complex that includes the bHLH protein E47 (probably BETA2/E47). Subsequent studies suggested that multiple regulatory elements interact with each other to elicit a full transcriptional response to glucose.¹⁶³ It has also been shown that the binding of the yet-to-be-characterized factor RIPE3b1 to its recognition sequence (the C1 box) in the rat insulin II promoter may be regulated by glucose.¹⁶⁴ The fact that RIPE3b1 DNA-binding activity is inhibited by the oxidizing agent diamide and the alkylating agent N-ethylmaleimide suggests that changes in the redox state of the cell may contribute to the regulation of the insulin promoter by nutrients.¹⁶⁵

There is also very strong evidence that the homeodomain transcription factor PDX1 plays a major role in linking nutrient metabolism in the β cell to the regulation of the insulin gene.^{166–168}

Melloul and colleagues¹⁶⁶ demonstrated that glucose stimulated the DNA binding activity of a factor (GSF) which was subsequently identified as PDX1.¹⁶⁹ Glucose activation of PDX1 occurred rapidly (within 10–15 minutes) and involved phosphorylation of the transcription factor.¹⁶⁷ The effects of glucose could not be mimicked by cyclic AMP-elevating agents or tumor-promoting phorbol esters, suggesting that neither cyclic AMP-dependent protein kinase nor protein kinase C was involved. The mechanism by which glucose stimulates PDX1 DNA binding activity and insulin promoter activity has recently been elucidated. It involves a stress-activated protein kinase pathway in which SAPK2 (also known as RK/p38) plays a critical role,¹⁷⁰ although this has been disputed.¹⁷¹ SAPK2 is a member of an expanding family of MAP kinase-related kinases that are activated in response to adverse stimuli such as heat, osmotic shock, ultraviolet light, and DNA-damaging reagents, and by proinflammatory cytokines that are produced under conditions of stress.¹⁷² In β cells, activation of the SAPK2 pathway by glucose involves phosphatidylinositol-3-kinase (PI-3-kinase), while activation by stress (e.g., treatment with sodium arsenite) is independent of PI-3-kinase. Interestingly, activation of recombinant PDX1 by SAPK2 *in vitro* is associated with an increase in molecular mass from 31 kd to 46 kd. This increase in mass is also seen *in vivo*, where the 31-kd form of PDX1 is present in the cytoplasm of low glucose treated islets. Upon transfer to high glucose, PDX1 is rapidly (within 10–15 minutes) converted to an active phosphorylated 46-kd form that is present predominantly in the nucleus.^{173,174} Other metabolizable nutrients that induce insulin secretion (including xylitol, fructose, and pyruvate), as well as insulin itself, activated PDX1 DNA-binding activity and insulin promoter through PI-3-kinase.¹⁷⁵ It is unclear whether the effects of glucose and insulin are additive or whether glucose activates PI-3-kinase and insulin gene transcription by stimulating insulin secretion that then acts via an autoregulatory loop.¹⁷⁶

Glucose and other nutrients stimulate the biosynthesis of proinsulin^{177,178} and a number of other proteins, including the secretory granule membrane protein SGM110¹⁷⁹ and chromogranin A.¹⁸⁰ There may be a general, but relatively weak, stimulatory effect on the synthesis of a large number of islet proteins, along with a rapid and strong stimulation of proinsulin biosynthesis.¹⁸¹ The biosynthesis of proinsulin is coupled to secretion insofar as many insulin secretagogues also stimulate proinsulin biosynthesis. However, the transducing systems differ in a number of respects. First, glucose-stimulated insulin release is inhibited in a Ca^{2+} -free medium, whereas biosynthesis is still activated. Second, tolbutamide and phosphodiesterase inhibitors, such as isobutylmethylxanthine (IBMX), potentiate glucose-stimulated insulin release by increasing islet cyclic AMP levels, but do not affect proinsulin biosynthesis. Third, the threshold for glucose-stimulated insulin secretion (4.2–5.6 mmol) is higher than that for proinsulin synthesis (2.5–3.9 mmol). The point of divergence appears to occur early in the β -cell metabolic signaling pathway.¹⁸²

The molecular mechanisms whereby glucose stimulates translation of preproinsulin mRNA are not well understood. Translation initiation factors may be involved. The activity of the guanine exchange factor eIF2B is stimulated rapidly (within 15 minutes) and over the same range of glucose concentrations that stimulate proinsulin synthesis.¹⁸³ EIF2B facilitates the exchange of GTP between inactive and active forms of eIF-2, the factor involved in mediating the binding of the initiator Met-tRNA to the 40S ribosomal subunit. In other systems the activity of eIF2B is

modulated by phosphorylation of its subunit eIF2 α ; however, in islets, glucose stimulates eIF2B by an alternative mechanism that does not involve phosphorylation of eIF2 α . Another factor, eIF4E-BP1, which is also known as PHAS-1, is phosphorylated in response to glucose in β cells.¹⁸⁴ EIF4E-BP1 is a protein that binds and inhibits the activity of eIF4E, a component of the mRNA cap site recognition complex. Phosphorylation of eIF4E-BP1 causes it to dissociate from eIF4E. Glucose-stimulated phosphorylation of eIF4E-BP1 is dependent on the presence of amino acids, and may be mediated via insulin acting on the β cell. Thus, as for effects on insulin secretion and gene transcription, insulin release from the β cells may activate an insulin-receptor signaling pathway to autoregulate its own biosynthesis. The activated eIF4E forms part of a complex that in addition to recognizing the mRNA cap site, also unwinds secondary structure within the 5' untranslated region of the mRNA. The selective effects of glucose on proinsulin may therefore be based on the presence of stem loop structures within the 5'UTR of preproinsulin mRNA.¹⁸⁵

The Insulin Gene and Diabetes Mellitus

There are several aspects of the regulation of insulin gene expression and β -cell transcription factors that may relate to a better understanding of the development of type 1 (T1DM) and type 2 diabetes mellitus (T2DM). As a result of a genome-wide search, a number of loci (around 18) that confer susceptibility to T1DM have been described.¹⁸⁶ Of these, the T1DM 1 locus within the major histocompatibility complex on chromosome 6p21, and the T2DM 2 locus within the insulin gene region on chromosome 11p15 have the most powerful effects. The T2DM 2 locus has been further mapped and identified as allelic variations in the insulin VNTR. There are two main classes of VNTR allele: class I (26–36 repeats) and class III (140–200 repeats). The class I VNTRs confer an increased risk of T1DM, while class III VNTRs are dominantly protective.¹⁸⁷ As described above, the VNTR (or ILPR) is transcriptionally active in β cells,^{188,189} with the shorter class I allele appearing to exhibit stronger transcriptional activity than the class III allele,¹⁹⁰ although not in all studies.¹⁸⁸ The reason why the class III allele should provide protection against T1DM has proved puzzling until it was recently discovered that insulin mRNA (along with that of other β cell autoantigens such as GAD, ICA69 and IA2) was expressed at low levels in human fetal thymus.^{191,192} In the thymus, as opposed to the β cell, the class III allele was associated with higher insulin mRNA levels. Expression of the insulin gene in the thymus may serve to enhance immune tolerance to proinsulin, which is a major autoantigen in T1DM, by deletion of autoreactive thymocytes or the generation of regulatory T lymphocytes. This would provide a plausible explanation for the protective influence of the class III VNTR allele in T1DM.

A number of lines of evidence suggest that the homeodomain protein PDX1 is a potential factor contributing to the pathogenesis of diabetes mellitus.¹⁹³ The key role of this transcription factor in islet cell ontogeny is emphasized by the demonstration that in mouse gene inactivation models¹²¹ and in a human subject with a homozygous mutation in the *pdx1* gene the pancreas fails to develop.¹⁹⁴ In the adult, PDX1 is expressed primarily in the β cell, where it regulates expression of a number of genes that are preferentially expressed in the β cell, including insulin, GLUT-2, glucokinase, and islet amyloid polypeptide. It also mediates the activation of the insulin gene by glucose (see above). In β cells cultured

for prolonged periods in high glucose, expression of the insulin gene is repressed,¹⁹⁵ as is expression of PDX1,¹⁹⁶ and another insulin gene regulatory protein, RIPE3b1.¹⁹⁷ This suggests that the glucotoxic effects of prolonged hyperglycemia on the β cell, as seen in T2DM, may be mediated in part by repression of PDX1.¹⁹⁸

Mutations in PDX1 have been found in patients with maturity onset diabetes of the young (MODY4),¹⁹⁹ a monogenic early onset form of T2DM. Three other forms of MODY have been described with mutations in the genes encoding glucokinase (MODY2),²⁰⁰ and the transcription factors HNF1 α (MODY3) and HNF4 α (MODY1).²⁰¹ The discovery of mutations in PDX1,^{202,203} HNF1 α , and HNF4 α in MODY families stresses the importance of transcription factors in the pathogenesis of certain forms of T2DM. This is further emphasized by the finding that heterozygous (+/-) *pdx1* mice injected intraperitoneally with 20 mmol glucose remained hyperglycemic for up to 2 hours, while normal control mice returned to euglycemia within this time period.²⁰⁴ As well as regulating development of the endocrine pancreas, PDX1 also appears to play a key role in glucose homeostasis in the adult. (See Chapt. 21).

MUTATIONS IN THE INSULIN GENE

H.S. Tager and his associates were the first to identify a structurally abnormal insulin in the circulation and pancreas of a patient with mild diabetes associated with elevated insulin levels.²⁰⁵ These and similar studies have led to the definition of a new clinical syndrome of familial mild hyperinsulinemic diabetes that is now considered to be a form of MODY, but often resembles T2DM.^{206,207} Affected individuals have high circulating immunoreactive insulin levels and decreased C peptide:insulin ratios, resulting most likely from the delayed turnover, *in vivo*, of circulating insulin variants due to their impaired receptor binding properties.²⁰⁸ The disorder is inherited in an autosomal dominant fashion within families, consistent with the Mendelian distribution of a defective allele.

In all cases studied a single nucleotide substitution occurs in only one of the two insulin gene alleles, leading to a single amino acid replacement within the insulin molecule.^{207,209,210} The abnormal insulins generated by these missense mutations are all characterized by a very low binding potency, below 5% of normal, as demonstrated by direct assays.^{211,212} However, the replacements occur at different sites within the insulin molecule [at residues B24 (Phe $\rightarrow$ Ser), B25 (Phe $\rightarrow$ Leu), and A3 (Val $\rightarrow$ Leu)], and the affected individuals thus far have all been heterozygous for the defective gene. It is evident from the high incidence of mild diabetes or glucose intolerance among the affected individuals in these families that the presence of a defective insulin allele can be a significant predisposing factor to the development of diabetes.

Other insulin variants have been identified that give rise to elevated circulating proinsulin, with or without clinically significant carbohydrate intolerance.^{213,214} These families also exhibit an autosomal dominant pattern of inheritance, and in several cases the defect has been localized to the C peptide-A chain conversion site in the proinsulin molecule, where the arginine of the Lys-Arg pair recognized by the converting enzyme has been replaced by another amino acid (histidine or leucine), rendering this site uncleavable.^{215,216} A very rare form of hyperproinsulinemia in which a point mutation changes the histidine at position 10 of the B chain to aspartic acid has also been identified in one family.^{217,218} This is a

particularly interesting mutation since the resultant proinsulin molecule retains the normal paired basic residues, but is not processed efficiently due to a defect in its sorting into secretory granule: which leads to its increased secretion as intact proinsulin via constitutive pathways.^{219,220} In this case the insulin (or proinsulin) has approximately fourfold elevated relative receptor binding potency and there is no evidence of its association with diabetes.

The study of insulin variants has led to significant revisions in previous theories regarding the location of the receptor binding region in the insulin molecule, as discussed earlier, and has also provided direct evidence that receptor-mediated uptake and degradation of insulin²²¹⁻²²³ is a major pathway of insulin metabolism *in vivo*. The frequency of insulin gene mutations in diabetic populations appears to be quite low, probably less than 0.1% of patients.

Recent studies using the new technique of SSCP (single strand conformational polymorphism) analysis to characterize variability in the insulin gene in 100 African-Americans with T2DM have revealed the existence of significant variations in the promoter region and exons 1, 2, and 3.^{224,225} No significant variants were found in any of the coding sequences, although a silent G to A substitution (allele frequency, 6%) was detected in the codon for Ala10 of the signal peptide. Several promoter variants were also found, some of which exhibited significantly reduced insulin promoter activity (38-44% of normal). Thus naturally occurring promoter variants that reduce insulin gene expression may contribute to a small proportion of diabetics in some ethnic groups. (See reference 15 for more information on insulin gene mutations.)

IAPP/AMYLIN: A NEW SECRETORY PRODUCT OF THE β CELL

Evidence has accumulated indicating that β cells secrete small amounts of a number of other peptides and proteins in addition to insulin. Some of these are unique to the islet β cells, while others, such as chromogranin A, are expressed in other neuroendocrine cells and neoplasms.^{29,226} The role of these accessory secretory proteins is not understood, but they may have roles in normal physiology or in the formation and organization of the secretory granule and/or the processing of prohormones.

Considerable recent attention has been focused on one of these in particular, a novel neuropeptide-like molecule known as islet amyloid polypeptide (IAPP), or amylin (Fig. 3-9). This peptide was first identified as a major protein constituent of the amyloid

FIGURE 3-9. Primary structure of human islet amyloid polypeptide (IAPP or amylin).

FIGURE 3-10. A. Schematic structure of the precursor of human islet amyloid polypeptide (IAPP). The arrows indicate the cleavage sites for generating the mature IAPP sequence. B. Schematic representation of the mRNA encoding preproIAPP, indicating its relation to the exons of the IAPP gene. C. Comparison of IAPP and CGRP gene structures. The ancestral gene of this superfamily may have been organized similarly to that of the CGRP-2 gene. 5'UT, 5' untranslated region; SP, signal peptide; CT, calcitonin.

deposits that occur in the islets of elderly diabetics (those having type 2 diabetes, previously called non-insulin-dependent diabetes mellitus) and in many benign insulinomas of the pancreas, as well as in the normal pancreata of elderly individuals (see Chap. 17).²²⁷⁻²³⁰ The presence of amyloid-like material was first observed in diabetic human pancreata as early as 1901 by the pathologist Opie,²³¹ but it was not until 1986 that this material was successfully extracted for analysis.²²⁷ When soluble extracts were analyzed, they were found to consist of a single peptide, IAPP, which when sequenced turned out to be related to the 37-amino-acid neuroendocrine peptides calcitonin gene-related peptide (CGRP) 1 and 2 (Fig. 3-10).²²⁷⁻²³⁰ The CGRP-1 is a second product of the calcitonin type I gene, derived through an alternative splicing event that occurs mainly in neural tissues.²³²⁻²³⁴ As a result of this process, a calcitonin-encoding exon (exon 4) is replaced by another encoding CGRP (exon 5) to produce an mRNA encoding a preproprotein that gives rise to CGRP via proteolytic processing at paired basic residues.²³³

The decoding of the amino acid sequence of IAPP led to the identification of both the cDNA and the chromosomal gene encoding this hormone-like polypeptide in man.²³⁴⁻²³⁸ In addition, cDNAs encoding IAPP precursors from a number of mammalian species have been described.^{235,236,239} PreproIAPP is a typical neuroendocrine precursor having a signal peptide followed by a short propeptide ending in Lys.Arg before the IAPP sequence, which is then followed by Gly.Lys.Arg and another short propeptide region (Fig. 3-10A). The glycine residue at the C terminus of the IAPP

domain in the precursor is the hallmark signal for carboxyamida-tion, a feature also seen in the CGRPs.^{235,239} Comparison of the sequences of several mammalian IAPPs and CGRPs revealed extensive sequence similarities, but also canonical sequence differences. This pattern suggests that separate, but related, tissue receptors may exist for these peptides. The single gene encoding IAPP in man (Fig. 3-10C) is located on the short arm of chromosome 12,^{237,238} which is believed to be an evolutionary homologue of chromosome 11, where the CGRP-1 and -2 genes are located.²³² Thus the available evidence strongly supports the divergence of IAPP, CGRP, and calcitonin from a common ancestral gene.

Biosynthesis and Levels of IAPP in Islets

The IAPP precursor is transferred along with proinsulin into newly forming secretory vesicles in the *trans* Golgi of the β cells, where it is then processed by the same enzymatic machinery as proinsulin to release the mature 37-residue carboxyamidated peptide. It is then stored in the insulin granules and subsequently secreted together with insulin.²⁴⁰ Very low levels of IAPP mRNA have also been detected in the stomach and other regions of the gastrointestinal tract, in the lung, and also in the dorsal root ganglia of the spinal cord.²⁴¹

The relative levels of IAPP in the β cell appears to be only a few percent of the level of insulin. High-performance liquid chromatography (HPLC) analysis of freshly isolated rat islets shows amounts of IAPP that are in the range of 1-2% those of insulin.²⁹

Biosynthetic labeling experiments in islets have also corroborated these low levels of IAPP expression relative to insulin [R. Carroll and D.F. Steiner, unpublished results]. Most studies²⁴²⁻²⁴⁴ agree that the levels of IAPP are in the range of 0.2–3% of the level of insulin in normal adult rat islets or normal human pancreas. Studies with isolated rat islets have shown that IAPP secretion is stimulated by glucose and that IAPP amounts to about 5% of the amount of insulin released in 1 hour at 16.7 mmol glucose (see Chap. 21).²⁴⁴

The question of whether IAPP inhibits insulin secretion from the islets of Langerhans has been controversial because the doses required for this effect in most studies are relatively high. However, recent studies on IAPP knockout mice lend support to this idea.²⁴⁵ Both male and female IAPP^{-/-} mice have normal basal levels of circulating insulin and glucose, but males exhibit an increased insulin response to glucose administration and more rapid glucose disappearance in oral and IV glucose tolerance tests. These findings indicate an autocrine or paracrine suppression of insulin secretion by IAPP under normal physiological conditions. Interestingly, male IAPP-deficient mice showed a 20% increase in body mass, possibly as a consequence of increased insulin secretion or an effect of IAPP on food intake^{246,247} (see Chap. 10).

IAPP inhibits insulin-stimulated glucose uptake and glycogen synthesis in rat muscle *in vitro*, an effect it shares with CGRP.^{248,249} In whole animals, efforts to modify glucose tolerance with IAPP infusion have met with mixed success but usually require supra-physiologic doses of IAPP. In IAPP knockout mice, insulin sensitivity was not altered in insulin tolerance tests.²⁴⁵ Other observed effects of IAPP are vasodilation, an effect it shares with CGRP, and lowering of serum ionized calcium, an effect it shares with calcitonin. IAPP can produce hyperglycemia in rats, evidently through mobilization of muscle glycogen to lactate, and thus might synergize with glucagon to enhance its hyperglycemic effects. This hyperglycemic effect has not been observed in humans treated with IAPP. Its major *in vivo* effect is a strong inhibition of gastric emptying and inhibition of glucagon secretion^{250,251} at physiologic levels, which is under consideration as a potential treatment for diabetes.

In summary, studies thus far suggest that IAPP may exert a mild insulinostatic effect in the islets. It also has a glucagonostatic effect which may be mediated via the CNS through efferent vagal activity.²⁵¹ Because of its structural relatedness to CGRP, IAPP at pharmacological levels may interact with CGRP receptors to produce some of the peripheral effects that have been attributed to it. Recent efforts to identify amylin receptors indicate the existence of a novel mechanism for regulating its actions via receptor activity-modifying proteins, or RAMPs, which interact with certain calcitonin receptor isoforms to generate high-affinity IAPP receptors.²⁵²⁻²⁵⁴ Seven helix receptors with high intrinsic IAPP binding affinity have not yet been unambiguously identified, but binding is high in the nucleus accumbens and several other brain areas^{255,256} that are accessible via the systemic circulation. However, much further study will be required to clarify the mechanism and physiological significance of these observations.

Mechanisms of Amyloid Formation

Several studies²⁵⁷⁻²⁵⁹ have indicated that islet amyloid formation occurs more prominently in spontaneously diabetic animals and preferentially in certain species, including man and several species

of nonhuman primates, as well as cats and raccoons. Interesting the IAPP sequences in these species differ most significantly in a region that has been defined as amyloidogenic (residues 20–29) studies of Glenner and associates²⁶⁰ and of Westermarck and coworkers²⁶¹ (see Chap. 17).²³⁹ Synthetic peptides from this region had the greatest tendency to form fibrillar stacked β pleated sheet structures similar to those occurring in amyloid. Although in normal β cells, IAPP is localized within the insulin secretory granules,^{262,263} fibrillar immunoreactive amyloid deposits have been noted primarily extracellularly, although some have been reported within the cytoplasm of β cells of some patients with T2DM. Clark and colleagues.²⁶⁴ Others have noted the proximity of amyloid deposits to the β cells, suggesting that it has arisen from the cells either by secretion or some other means of deposition.²⁶¹ Clark and associates²⁶⁶ have found IAPP immunoreactivity in lysosomes and lipofuscin bodies within the β cells of the islets of both normal and diabetic individuals and have suggested that amyloid may begin to form during the intracellular degradation of secretory granules, as occurs in the normal turnover of unused secretory products, a process known as crinophagy.

Transgenic mice overexpressing the human isoform of IAPP in their β cells *in vivo* by driving expression with the rat insulin I gene promoter have been reported to form amyloid deposits in some strains, but not in others.²⁶⁷⁻²⁷⁰ However, when cultured *in vitro* at elevated glucose concentrations or implanted under the renal capsule in nude mice, islets from transgenic mice expressing human IAPP produce extracellular deposits typical of amyloid fibrils.²⁷⁰⁻²⁷² Human islets implanted in nude mice also rapidly develop islet amyloid deposits, especially with hyperglycemia, raising a possible caveat to some human islet transplantation strategies in diabetes. One possible factor in *in vivo* fibril formation is the degree of elevation of the level of expression of hIAPP in the mouse β cells. More recent studies have shown that high-fat diet and hyperglycemia favor the formation of islet amyloid deposits in hIAPP transgenic mice.²⁷⁴ The intragranular environment also influences the formation of hIAPP fibrils,²⁷⁵ hence alterations associated with hyperglycemia and/or diabetes may favor the nucleation of deposits.

Just why diabetes leads to amyloid deposition remains unclear,²⁷⁶ but the reason may be related to hypersecretion of IAPP associated with hyperglycemia in conjunction with other as yet unknown factors that may enhance β fibril accumulation, such as disturbed islet microcirculation. Although earlier studies failed to reveal any abnormalities in the predicted sequence of IAPP precursors in 25 type 2 diabetic patients,²⁷⁷ a more recent study reported a Ser $\rightarrow$ Gly mutation at position 20 of IAPP in 4.1% of Japanese patients with type 2 diabetes.²⁷⁸ Thus abnormalities in the structure of IAPP or its precursor forms may occur, but are likely to be a minor contributing factor to diabetes. A more interesting possibility is that altered proteolytic processing of proIAPP by P and PC3 may occur under certain conditions,²⁷⁹⁻²⁸¹ giving rise to incompletely processed intermediate products with altered aggregation properties and/or bioactivity. Amyloid deposits occur in the islets during normal aging and appear to be similar to those in diabetic subjects, but are usually much less abundant.^{282, 283}

Beta-Cell Function and Insulin Secretion

Bo Ahren

Gerald J. Taborsky, Jr.

In this chapter we shall describe the mechanisms by which the beta cells (B cells, β cells) of the islets of Langerhans of the pancreas synthesize and secrete insulin in response to changes in the metabolic state of the organism. Although insulin is made by the same peptide synthetic mechanisms as in other cells, β cells are unique in that insulin synthesis is stimulated by increases in the blood glucose level. Furthermore, β cells possess a complex set of mechanisms (Fig. 4-1) by which glucose metabolism controls membrane electrical activity, calcium uptake, and insulin release. The β cell is also remarkable in its sensitivity to a host of other plasma metabolites, hormones, and neurotransmitters that participate in the control of peripheral metabolism. The β cell integrates input from these stimuli to synthesize and secrete the amount of insulin needed to regulate plasma nutrient levels and systemic metabolic processes under a full range of physiologic conditions.

ANATOMY OF THE ISLETS OF LANGERHANS

β Cells and Other Endocrine Cells

In all mammalian species, pancreatic β cells are found in the islets of Langerhans,¹ which are discrete clusters of endocrine cells scattered throughout the pancreas but found most abundantly in the tail of the pancreas. Although both pancreatic endocrine and exocrine cells are important for fuel absorption and metabolism, their nearly universal anatomical association remains largely unexplained. The islets number from 100,000–2,500,000 per pancreas, vary in size from about 50–300 μm in diameter, and contain from hundreds to a few thousand hormone-secreting endocrine cells. A delicate connective tissue sheath separates the islet cells from the acinar cells of the surrounding exocrine pancreas. Islets receive sympathetic and parasympathetic nerves and are maintained by an arterial blood supply that branches into a rich, intraislet capillary bed. Venous efferents from smaller islets pass through neighboring pancreatic exocrine acini before emptying into the portal venous system; efferents from larger islets pass directly to the portal system. Islet hormones therefore arrive in high concentrations in the liver and parts of the exocrine pancreas before reaching peripheral tissues. Because the liver degrades and clears a large fraction of the insulin that it receives, peripheral insulin levels are considerably lower than found in the portal vein.

The islets are a densely packed collection of peptide-secreting endocrine cells, all of which are involved in metabolic regulation.

The insulin-secreting β cells are the most abundant and constitute from 70–90% of islet endocrine cells. The less numerous α cells (or A cells) secrete glucagon and make up the bulk of the remaining cells. The remaining islet cells include δ cells (or D cells), which secrete somatostatin, and F cells, which secrete pancreatic polypeptide (PP). In rodent islets, but less obviously in human islets, β cells tend to be located in a central core with α cells nearer the islet's surface along with δ and F cells. The various islet secretory cells are packed very closely together with a common, but very narrow extracellular space that may allow hormones secreted by one cell to diffuse directly to other cells and affect their behavior in a "paracrine" manner. Further intraislet communication and coordination between islet cell types is also possible via cell-cell gap junctions, which can conduct small molecules and bioelectrical signals.

All islet cell types share the classic features of other peptide-secreting cells. The β cells are from 10–15 μm in diameter and have a prominent nucleus, rough endoplasmic reticulum (RER) and Golgi apparatus. As described in Chap. 5, these structures synthesize, package, and store the peptide hormones in numerous membrane-bound secretory granules (known as secretory vesicles), which share the cytoplasmic space with a large complement of mitochondria. Although the various islet cell types are remarkably similar in most details, the appearance of the quarter-micron-diameter (250 nm) secretory granules differs. The insulin in β -cell granules appears as electron-dense crystals surrounded by an electron-lucent halo. Glucagon in α -cell granules more nearly fills the granular space with an electron-dense spherical core. The cores of δ - and F-cell granules are spherical but much less dense in appearance.

Circulatory, Neural, and Intraislet Inputs

The islet arterial blood supply is carried through a neurovascular stalk before breaking into arterioles. The arterioles pass through the non- β -cell rim before bifurcating into fenestrated capillaries which pass into the β -cell-rich islet interior. Morphological work suggests that β cells are polarized such that afferent capillaries first pass the cell side, which is presumably enriched with various membrane receptors. After passing several β cells in this manner the capillaries turn back toward the islet surface and pass the secretory poles of the β cells, where insulin is secreted and diffuses into the capillary. Plasma containing freshly secreted insulin is then carried to the receptor poles of α cells, and then δ cells (and F cells) as the capillaries approach the islet's surface. Glucagon

FIGURE 4-1. A simplified schematic view of signaling pathways in the β cell activated by external stimuli. All illustrated receptors are not always expressed in the same β cells. Abbreviations: AA = arachidonic acid, AC = adenylate cyclase, ACh = acetylcholine, ADP = adenosine diphosphate, ATP = adenosine triphosphate, CaMK = calmodulin kinase, cAMP = cyclic adenosine monophosphate, CCK = cholecystokinin, CPT-1 = carnitine palmitoyl transferase-1, DAG = diacylglycerol, ER = endoplasmic reticulum, FFA = free fatty acid, G-6-P = glucose-6-phosphate, GLP-1 = glucagon-like peptide-1, GLUT-2 = glucose transporter 2, GRP = gastrin-releasing polypeptide, IGF-1 = insulin-like growth factor-1, IP₃ = inositol-1,4,5-trisphosphate, IRS-1 = insulin receptor substrate-1, IRS-2 = insulin receptor substrate-2, LC-CoA = long-chain coenzyme A, PACAP = pituitary adenylate cyclase-activating polypeptide, PDE3B = phosphodiesterase 3B, PI-3-K = phosphatidylinositol-3-kinase, PIP₂ = phosphatidylinositol-4,5-bisphosphate, PKA = protein kinase A, PKB = protein kinase B, PKC = protein kinase C, PLA₂ = phospholipase A₂, PLC = phospholipase C, SUR = sulfonylurea receptor, TCA = tricarboxylic acid cycle, TG = triglyceride pool, VIP = vasoactive intestinal polypeptide. For further details, see text.

and somatostatin (and pancreatic polypeptide) are secreted and enter the plasma stream by diffusing into superficial venules lying underneath the islet's capsule. The implication of this vascular arrangement is that β cells, which are stimulated by glucagon and inhibited by somatostatin, may respond to circulating, but not locally secreted, glucagon and somatostatin. Superficial α and δ cells, on the other hand, may respond to locally secreted insulin, which reaches them either by the intraislet capillary circulation or by diffusion (a paracrine effect).

Parasympathetic and sympathetic nerves of the autonomic nervous system also pass through the islet's neurovascular stalk. These nerves do not form classical synapses with islet cells, but do

have specialized release sites as they pass near islet cells. Via these nerves, the central nervous system modulates islet hormone release using a variety of neurotransmitter receptor mechanisms; muscarinic receptors for acetylcholine (ACh) released from parasympathetic nerves can potentiate glucose-induced insulin release. Activation of α -adrenergic receptors by norepinephrine (from sympathetic nerves) and epinephrine (from the adrenal medulla) inhibits insulin secretion, while activation of β -adrenergic receptors (by the same neurohormone) stimulates insulin secretion. β cells also possess a variety of receptors for neuropeptides that may be coreleased with the classical autonomic neurotransmitters. For example, in some species galanin inhibits, and vasoactive intestinal

FIGURE 4-1. A simplified schematic view of signaling pathways in the β cell activated by external stimuli. All illustrated receptors are not always expressed in the same β cells. and somatostatin (and pancreatic polypeptide) are secreted and enter the plasma stream by diffusing into superficial venules lying underneath the islet's capsule. The implication of this vascular arrangement is that β cells, which are stimulated by glucagon and inhibited by somatostatin, may respond to circulating, but not locally secreted, glucagon and somatostatin. Superficial α and δ cells, on the other hand, may respond to locally secreted insulin, which reaches them either by the intraislet capillary circulation or by diffusion (a paracrine effect).

Parasympathetic and sympathetic nerves of the autonomic nervous system also pass through the islet's neurovascular stalk. These nerves do not form classical synapses with islet cells, but do

have specialized release sites as they pass near islet cells. Via these nerves, the central nervous system modulates islet hormone release using a variety of neurotransmitter receptor mechanisms; muscarinic receptors for acetylcholine (ACh) released from parasympathetic nerves can potentiate glucose-induced insulin release. Activation of α -adrenergic receptors by norepinephrine (from sympathetic nerves) and epinephrine (from the adrenal medulla) inhibits insulin secretion, while activation of β -adrenergic receptors (by the same neurohormone) stimulates insulin secretion. β cells also possess a variety of receptors for neuropeptides that may be coreleased with the classical autonomic neurotransmitters. For example, in some species galanin inhibits, and vasoactive intestinal

polypeptide (VIP), pituitary adenylate cyclase-activating polypeptide (PACAP) and gastrin-releasing polypeptide (GRP) stimulate, insulin secretion (see Chap. 8). Islets are also innervated by sensory nerves, which contain the neuropeptides, substance P, and calcitonin gene-related peptide (CGRP). These sensory nerves reach the spinal cord via the splanchnic nerves.³ Studies with the neurotoxin capsaicin, which destroys small unmyelinated sensory nerve fibers, result in a potentiation of glucose-stimulated insulin secretion in mice, suggesting that they tonically restrain insulin secretion.⁴

INTRACELLULAR CONTROL OF INSULIN SYNTHESIS AND SECRETION

Synthesis and Packaging in Secretory Granules

As in other peptide-secreting cells, β cells synthesize insulin via a complex process (see Chap. 3) that begins with transcription of the DNA insulin gene to messenger RNA (mRNA) in the cell nucleus. Glucose stimulates the transcription of both human and rodent insulin genes, as does glucagon-like peptide 1 (GLP-1).⁵ Some of this stimulation occurs through a cyclic AMP response element in the insulin gene promoter,⁶ and some stimulation occurs through trans-activation factors,⁷ such as islet duodenum homeobox-1 (IDX-1), pancreas duodenum homeobox-containing transcription factor-1 (PDX-1), and fibroblast growth factor (FGF), and signals from developmental morphogenic proteins known as hedgehogs (Hh).⁷⁻⁹

In the ribosomes of the RER, the mRNA is translated to the large peptide preproinsulin. This process is stimulated by glucose through phosphorylation of two translation factors, called eIF-2B and PHAS-1/eIF-4E-BP.^{10,11} Glucose's stimulation of translation makes a significant contribution to preproinsulin synthesis.^{10,12} After preproinsulin is formed, the signal sequence (necessary for inserting the peptide into the RER) is cleaved, and the resulting proinsulin is transported to the Golgi apparatus by small membrane-bound vesicles. As the Golgi apparatus concentrates and packages the proinsulin into secretory granules, converting enzymes begin to cleave proinsulin to yield insulin and C peptide. Mature secretory granules contain equimolar amounts of mature insulin and C peptide, with residual amounts of unconverted proinsulin and proinsulin intermediates. The membrane-bound granules also concentrate zinc ions, which are essential for crystallizing the insulin, as well as protons that control the activity of the converting enzymes. Secretory granules have specific membrane proteins important for their docking to the plasma membrane. In addition they contain high levels of calcium, the monoamines, dopamine, and serotonin, as well as the 36-amino-acid peptide islet amyloid polypeptide (IAPP). IAPP is a fibrillogenic peptide which is the main constituent of the amyloid seen in islets of subjects with type 2 diabetes mellitus (T2DM).¹³ However, fibrils are not normally found in the secretory granules, because intragranular factors prevent fibril formation.¹⁴

Once formed, granules enter a large cytoplasmic granule storage pool. Only 1% of this pool is available for immediate release upon stimulation of the cell, probably because it is located immediately adjacent to the plasma membrane.¹⁵ The release of these granules is thought to constitute the first phase of insulin secretion seen within a few minutes after stimulation with glucose. This readily releasable pool of granules is refilled from the large reserve pool, which is thought to account for the second phase of insulin secretion.¹⁶ Granules undergo translocation from the reserve pool by

microtubules and microfilaments.¹⁷ The fusion of the granules with the plasma membranes requires ATP, is triggered by Ca^{2+} , and shows similarities to granule-membrane fusion in neurons.¹⁸ In the β cells, the secretory granular membrane protein synaptobrevin and the plasma membrane proteins, syntaxin and N-ethylmaleimide-sensitive factor attachment protein-25 (SNAP-25), play major roles in this fusion. Furthermore, the granule protein, synaptotagmin, seems to be responsible for the Ca^{2+} sensitivity of exocytosis in β cells.^{15,19} Older granules that are not secreted are degraded by fusion with lysosomes.

Intracellular Signals That Control Insulin Release

Once insulin is synthesized and packaged in granules, its exocytotic release is controlled by complex interactions of several signaling pathways within the β cell. This complexity allows integration of complex metabolic and physiologic information, resulting in an insulin secretory rate appropriate for regulating metabolism. Figure 4-1 classifies the major players in this regulation. Although the players will be familiar to students of other neural and secretory cells, it is safe to say that the pancreatic islet β cell is unique in the specialized way it uses these systems and in the degree to which these systems interact with each other. To a remarkable degree, the single cell is responsive to all types of neurohumoral and metabolic inputs, whereas other neurosecretory cells are generally specialized to respond to only a few inputs.

The most important function of the β cell is to respond to elevations of extracellular glucose by secreting enough insulin to restore a normal plasma glucose level. This basic pathway begins with mechanisms for glucose uptake and metabolism, which controls membrane ion fluxes and electrical activity. In turn these regulate the cytoplasmic free Ca^{2+} , which controls the rate of the exocytosis of insulin. This basic glucose-controlled secretory pathway for the β cell is modulated by other regulatory factors, including nutrient hormones, or neurotransmitters.

Once stimulated by glucose, β -cell insulin secretion can be augmented or inhibited by various neurohumoral inputs. Glucagon and other peptide hormones, as well as β -adrenergic agonists, augment insulin secretion via the cyclic AMP messenger system. Parasympathetic activation of muscarinic receptors augments secretion via the phosphoinositide messenger system. Inhibitory receptors for several neurohumoral agents such as galanin, somatostatin (Ss), and α -adrenergic agonists interact at several points in these processes. Insulin secretion is also controlled by pathways activated by insulin and IGF-1, and finally, intracellular lipolysis is of importance through the formation of lipid signals affecting exocytosis.

The following paragraphs describe these subsystems and how they respond to each other and to exogenous stimuli. After over 50 years of intense scrutiny, the β cell has only recently revealed some of these major findings. The full story will certainly be more complex and may remain confused by significant differences between the " β cells" from different species and from different transformed model β -cell lines used in the laboratory. The coverage here will of necessity be broad and pass over many secondary but important interactions and effects.

Glucose Uptake and Metabolism

The β cell's specialization for regulating blood glucose levels in the normal range (roughly 90 mg/dL or 5 mmol) begins at the

first two steps. Glucose is transported into the β cell by the same insulin-insensitive facilitated transporter, GLUT-2, which is also found in the liver.²⁰ Although there are other glucose transporters in β cells, GLUT-2 carriers provide the high-capacity, low-affinity transport needed to nearly equilibrate glucose concentrations across the cell membrane to support the β cell's very high metabolic rate. The initial phosphorylation of glucose is by an islet-specific, low-affinity glucokinase with high capacity,²¹ mutations of which are diabetogenic in certain populations of patients with maturity-onset diabetes of the young (MODY).²² Although also present, hexokinase, which has a higher affinity for glucose, is largely inhibited. Thus, low-affinity glucokinase becomes the predominant path and effectively desensitizes β -cell glycolysis to glucose stimulation such that half-maximal and maximal levels of glycolytic metabolism, although higher than in most other cells, require much higher levels of glucose. This in effect raises the threshold for subsequent metabolic signaling to other cellular subsystems.²¹ Following phosphorylation of glucose and further metabolism, pyruvate is formed that is taken up by the mitochondria for oxidation. In fact, more than 90% of glucose-derived carbons are oxidized in the mitochondria.²³ Through metabolism in the tricarboxylic acid cycle and transfer of reducing equivalents to the electron transport chain, ATP is generated. This will raise the cellular ATP:ADP ratio, which is a key mechanism for the closure of the specific K_{ATP} channels.

Membrane Ion Fluxes and Electrical Activity: K_{ATP} Channels and Ca Channels

Since it was first discovered in 1968,²⁴ the triggering of β -cell membrane electrical activity by glucose metabolism is now understood to be an obligate step in the stimulus-secretion coupling of glucose-induced insulin secretion. The key metabolic-ionic link is the ATP-sensitive potassium channel (K_{ATP}),²⁵⁻²⁷ which also renders hypothalamic neurons, vascular smooth muscle, and myocardial cells sensitive to their metabolic states. The β -cell K_{ATP} channels are octamer complexes composed of four pore-forming Kir6.2 subunits, which form an inward rectifier K^+ channel comprised of 390 amino acids and four sulfonylurea receptor (SUR1) subunits.²⁸⁻³⁰

β -Cell K_{ATP} channels are tonically open and maintain the β -cell resting membrane potential near the potassium equilibrium potential (near -60 mV). The channels, however, have two important receptors regulated by β -cell metabolism. One receptor is the Kir6.2 subunit, which binds free ATP (or free ADP, but at tenfold lower affinity) and closes the channel, thus allowing the cell to depolarize. SUR1, the second receptor subunit, binds nucleotide diphosphates in the presence of Mg^{2+} (such as Mg -ADP) and increases channel opening, competing with the closing effect of free ATP. Thus, increasing glucose levels will convert more ADP to ATP through glycolytic and oxidative metabolism so that the opening effect of Mg -ADP is reduced to reveal the closing effect of free ATP.^{31,32} The net closure of K_{ATP} channels depolarizes the β -cell membrane.

Studies in genetically engineered mice either expressing a dominant negative form of Kir6.2 in the β cells or lacking Kir6.2 have demonstrated that the K_{ATP} channels are the major determinant of the resting membrane potential in the β cells and that normal insulin secretion after glucose requires these channels. Furthermore, even though Kir6.2 knockout mice develop only mild glucose intolerance, fasting hyperglycemia is seen in aged and obese mice lacking Kir6.2.³⁰ Interestingly, a mutation of either the SUR1 gene or, less commonly, the Kir6.2 gene, both of which are

located on chromosome 11, causes defective function of K_{ATP} channels, which is associated with the persistent hyperinsulinemic hypoglycemia of infancy.^{30,33}

K_{ATP} Channels are also targets for clinically important anti-diabetic compounds, sulfonylureas, because they close K_{ATP} channels by binding to the SUR1,^{23,34} as do the newly developed anti-diabetic agents repaglinide and nateglinide.^{35,36}

The depolarization due to closing of K_{ATP} channels opens voltage-dependent calcium (Ca) channels. At a threshold level of glucose near 5 mmol, the glucose-induced membrane depolarization (to about -60 mV) is sufficient to trigger the opening of voltage-dependent L-type calcium channels in the β -cell membrane. This admits extracellular Ca^{2+} into the intracellular pool of free Ca^{2+} , where it interacts directly with the insulin exocytotic machinery to fuse the insulin secretory granules to the plasma membrane and release insulin.

The opening of Ca^{2+} channels is, however, coordinated to produce rhythmic oscillations³⁷ of membrane potential consisting of trains of Ca^{2+} action potentials (at frequencies between 4 and 12 spikes per second) superimposed on depolarized "plateau" potentials. At low, suprathreshold levels of glucose (~ 6 mmol) the plateaus are brief (about 1–2 seconds long) and separated by "silent phases" lasting about 10 seconds. At levels of glucose that are half-maximal for insulin secretion, the plateaus last longer (5–10 seconds) and the silent phases are brief (about 5 seconds). At maximal levels of glucose (>15 to 20 mmol), the silent phases are abolished altogether and the cell remains depolarized and spikes persistently. The rhythmic pacing of Ca^{2+} uptake during the bursts of Ca^{2+} spikes is paralleled by oscillations of the free Ca^{2+} level with the cells that are synchronized throughout the islet by electrical coupling.^{38,39} The progressive increase in the Ca spiking activity as glucose increases underlies the increase of Ca^{2+} uptake seen in Ca^{2+} flux studies. The cause of the modulation is the progressive closure of K_{ATP} channels as the glucose metabolic rate increases with the increased glucose stimulation.

One hypothesis⁴⁰ is that the spike-and-burst pattern results from two functionally distinct L-type Ca^{2+} channels (drawn as a single channel for simplicity in Fig. 4-1). The spike channel activates rapidly and is closed almost as rapidly (within tens of milliseconds) by the rapid accumulation of intracellular calcium. The plateau Ca^{2+} channel also activates rapidly to produce the persistent plateau depolarization, but closes much more slowly (in seconds) in a depolarization-dependent manner to finally terminate the plateau. Both Ca^{2+} channels appear to contribute to the Ca^{2+} uptake required for insulin secretion. Another class of β -cell K^+ channel (not shown in Fig. 4-1) is the delayed rectifier K channel, which, as for nerve action potentials, assists in repolarizing the Ca^{2+} spike.⁴¹

Calcium Metabolism

The calcium accumulated during the spiking plateau phase is pumped out of the cell by membrane Ca-ATPase pumps. In addition, free Ca^{2+} is taken up and stored by the cell's endoplasmic reticulum (ER), where it can be released when inositol-1,4,5-trisphosphate (IP_3) and its related compounds activate specialized Ca^{2+} channels in the membrane of the ER. By providing additional substrate for the generation of IP_3 , glucose metabolism may further increase free Ca^{2+} levels. The parallel pathway increasing the formation of cyclic AMP may also be of importance for the increase in cytoplasmic Ca^{2+} after glucose activation because it has been demonstrated that cyclic AMP, through activation of protein kinase A (PKA), increases cytoplasmic Ca^{2+} by opening the voltage-dependent L-type Ca^{2+} channels.⁴²

An important consequence of the complexity of the calcium metabolic machinery is slow oscillations of free Ca^{2+} level, which occur with a period of 5–10 minutes, roughly 10–20 times slower than the frequency of the bursts of electrical activity described above. The oscillations may be of glycolytic origin, but membrane ionic channels and the phosphoinositide system are likely participants as well. The oscillations are observed as slow fluctuations of the intensity of membrane electrical activity,⁴³ intermediary metabolism, cytoplasmic free Ca^{2+} level, and insulin secretory activity.⁴⁴ These *in vitro* observations may explain the oscillations of islet secretory activity observed *in vivo*.^{45,46}

Insulin Secretion

The actual release of insulin occurs by exocytosis, a process in which the granule membrane fuses with the cell membrane. The membranes are disrupted at the point of fusion and the insulin crystal is discharged to the extracellular space, leaving the granule membrane and its proteins inserted into the cell's plasma membrane. The process of exocytosis is the rate-limiting step for physiologic insulin secretion, but its regulation is just now becoming understood. As in other secretory cells, cytoplasmic free Ca^{2+} concentration appears to be of paramount importance, yet the precise site of action and cofactors required for secretion are now only becoming known for a few model secretory systems. It is clear, however, for β cells, that several "second messenger" systems are critically important for controlling the secretory steps and for setting the sensitivity of the release sites to the prevailing free Ca^{2+} level. Furthermore, studies⁴⁷ indicate a yet to be identified signal(s) that depends on glucose metabolism that bypasses the Ca^{2+} metabolism step and allows glucose to potentiate the effects of Ca^{2+} on secretory rate.

To summarize the basic pathway for glucose-induced insulin secretion: First, glucose depolarizes β cells and triggers membrane electrical activity, which brings extracellular Ca^{2+} into the cell through voltage-gated Ca^{2+} channels. Second, glucose may generate IP_3 , which mobilizes Ca^{2+} from intracellular stores in the ER. Third, glucose inhibits the pumping of Ca^{2+} from the cytoplasm back to the extracellular space. Fourth, by an unknown pathway, glucose metabolism sensitizes the secretory machinery to the prevailing cytoplasmic Ca^{2+} level, allowing insulin secretion independent of changes in the K_{ATP} -channel activity or cytoplasmic Ca^{2+} level.⁴⁸

Calcium Messenger System

Raising cytoplasmic Ca^{2+} augments exocytosis through the activation of serine/threonine protein kinases. The mediators of this activation appear to be a family of proteins called calmodulins (CaMs). Of these, the Ca^{2+} /CaM-dependent protein kinase II (CaMK II) has been explored in most detail⁴⁹ with four isoforms found in islets.⁵⁰ Inhibition of CaMK II impairs nutrient-induced insulin secretion.⁵¹ Ca^{2+} also activates the myosin light-chain kinase (MLCK) and inhibition of MLCK may help to impair glucose-stimulated insulin secretion.⁵²

Phosphoinositide Messenger System

Glucose increases production of diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP_3) perhaps by providing additional phospholipid substrate or by activating membrane phospholipases. DAG and IP_3 are also formed by hydrolysis of phosphatidylinositol-bisphosphate (PIP_2) through the action of phospholipase C (PLC), which is of particular importance for eliciting insulin secre-

tion after activation of muscarinic or cholecystokinin (CCK) receptors.⁵³ Several PLC isoforms have been identified in β cells (PLC- β_1 , PLC- β , PLC- γ , and PLC- δ) and PLC activation is triggered by guanosine triphosphate-binding proteins. As in other cell types, DAG remains membrane-bound and activates protein kinase C (PKC). This family of enzymes acts as serine/threonine kinases to phosphorylate various β -cell proteins. Several different PKC isoenzymes may exist in the β cells, including the conventional forms that are Ca^{2+} -responsive (PKC- α , PKC- β , and PKC- γ), forms that are Ca^{2+} -unresponsive but DAG-dependent (PKC- δ , PKC- ϵ , PKC- η , and PKC- θ), and forms that are both Ca^{2+} -unresponsive and DAG-independent (PKC- ξ , PKC- λ , and PKC- μ).^{49,54} When PKC isoenzymes are activated, they translocate to the plasma membrane and phosphorylate β -cell proteins, which in turn modulate ion channels and augment cell metabolism, which affects insulin secretion. PKC is involved in the responses to activation of muscarinic receptors.⁵⁵

IP_3 , which is also formed through PKC activation, on the other hand, is soluble and is released into the cytoplasm, unlike DAG, where it interacts with the endoplasmic reticulum to release stored calcium. Various isomers and breakdown products of IP_3 , as well as other polyphosphoinositides such as inositol hexakisphosphate (IP_6),⁵⁶ have been described in a growing list of phospholipid metabolites that may modulate insulin secretion.

The main role of IP_3 is in transducing input to the β cells of secretagogues that activate PLC, like acetylcholine⁵⁷ or CCK.⁵⁸ This enhances glucose-induced insulin secretion, but does not stimulate release in the absence of glucose. In addition to mobilizing ER Ca^{2+} , muscarinic activation activates a membrane Na^+ channel,⁵⁹ which may explain its depolarizing effects on β cells.⁴² Also, the peptide secretagogues GLP-1 and PACAP have been shown to increase the β -cell uptake of Na^+ .^{60–62} The increased cytosolic Na^+ may increase the uptake of Ca^{2+} , thereby increasing cytosolic Ca^{2+} . The importance of Na^+ -induced insulin secretion for these secretagogues is illustrated by findings that removal of extracellular Na^+ reduces their insulin secretory ability.^{60,62}

Cyclic AMP Messenger System

Activation of adenylate cyclase by various peptidergic (glucagon, GLP-1, PACAP, VIP) and β -adrenergic stimuli converts ATP to cyclic AMP. Each of these stimuli has a receptor linked to adenylate cyclase by guanine-binding proteins (G proteins). cAMP in turn binds to the regulatory subunit of PKA, activating its catalytic subunit, which phosphorylates proteins. There are two different forms of PKA. One form has a regulatory subunit that is cytosolic, whereas the other type interacts with proteins in the plasma membrane and in the secretory granule. PKA phosphorylates GLUT-2, K_{ATP} channels, and L-type Ca^{2+} channels, all of which are involved in insulin secretion.^{63–65} However, activation of PKA is not sufficient to elicit insulin secretion after stimulation with glucose, but rather appears to potentiate the effect of other pathways. cAMP also can directly activate the exocytosis process since it augments insulin secretion in the absence of raised cytoplasmic Ca^{2+} .⁴²

Intracellular cAMP is also regulated by its phosphodiesterases (PDEs), which degrade the cyclic nucleotide. Three different isoforms of PDE (PDE1, PDE2, and PDE3) are expressed in islets. The most important of these is PDE3, which in turn exists in two different subtypes, PDE3A and PDE3B.⁶⁶ PDE3 is activated by protein kinase B (PKB), which in turn is activated by phosphoinositide-3-kinase (PI-3-K). Both these enzymes are expressed in the β cells.^{67,68} The inhibitory actions of IGF-1 on insulin secretion

may be mediated by activation of PDE through PI-3-K and PKB and the subsequent reduction of intracellular levels of cAMP.

Arachidonic Acid Messenger System

Glucose, muscarinic activation, and CCK have been shown to activate phospholipase A₂ (PLA₂), which hydrolyzes plasma membrane phospholipids, resulting in formation of arachidonic acid (AA).⁶⁹⁻⁷¹ At least two different isozymes of PLA₂ are expressed in the β cells: a Ca²⁺-dependent and a Ca²⁺-independent form, which seem to be of importance for insulin secretion under different conditions. Thus, activation by the muscarinic agonist stimulates the Ca²⁺-dependent PLA₂, whereas activation by CCK stimulates both the Ca²⁺-dependent and Ca²⁺-independent forms.⁷¹ The formed AA directly increases cytoplasmic calcium and results in the formation of prostaglandins and eicosanoids, which in turn can affect insulin secretion. Therefore, the AA messenger system may also be of importance for insulin secretion, although its relative contribution to the insulin responses to muscarinic activation and CCK is probably less than the PLC pathway.

Lipid Messenger System

Lipid-derived signals are also important for insulin secretion. These signals are long-chain acyl CoA (LC-CoA) derived from triglycerides stored in the β cells,^{72,73} and they augment the fusion of granules with the plasma membrane during exocytosis through activation of PKC.⁷³ Neurohormonal agents may therefore regulate the exocytosis of insulin through activating or inhibiting LC-CoA formation. One target for these agents is the hormone-sensitive lipase (HSL) which is expressed in the β cells.⁷⁴ HSL is activated by PKA; therefore, agents increasing cAMP might augment insulin secretion through HSL-mediated formation of LC-CoA, as has been proposed for GLP-1.⁷⁵

Insulin Messenger System

The insulin receptor is also expressed in the β cells.⁷⁶ Since previous data showed that exogenous insulin inhibits insulin secretion, it was thought that the β cells exhibit autocrine inhibition like some other secreting cells. However, the generation of β -cell-specific insulin-receptor-deleted mice have challenged this view. These mice develop a defective insulin response to glucose and progressive impairment of glucose tolerance.⁷⁷ Although the relevance of these findings for the physiological regulation of insulin secretion remains to be established, these mouse studies indicate that insulin's action on its β -cell receptors is important for maintaining normal β -cell function.⁷⁸

Inhibitory Receptors

The β cell bears receptors for a number of physiologically important inhibitory neurohumoral signals that are superimposed on the stimulatory pathways described. α -Adrenergic stimulation does not appear to act via adenylate cyclase⁷⁹ as in many other systems but has clear effects that hyperpolarize β cells and inhibit insulin secretion, apparently at the release site.⁸⁰ The hyperpolarization may be due to the activation of low-conductance G protein-linked potassium channels⁸¹ that may also be activated by galanin.⁸² Although both galanin⁸³ and somatostatin⁸⁴ activate K_{ATP} channels, it is not clear that these effects are critical since galanin⁸⁵ and somatostatin⁸⁶ also act directly on the secretory machinery to block insulin release. The adipocyte hormone leptin has also been shown to directly restrain insulin secretion.⁸⁷ This effect is induced by

opening K_{ATP} channels, activation of PDE to breakdown cAMP, or activation of transcription factors.⁸⁷⁻⁸⁹

EXTRACELLULAR CONTROL OF INSULIN SECRETION

Basal Insulin Secretion

Basal insulin secretion is defined *in vivo* as that which occurs in the absence of any exogenous stimulation of insulin release. The basal insulin level is usually measured in the morning after an overnight fast because by then the postabsorptive stimulation of insulin release is clearly over and the circulating levels of metabolic and gut hormone secretagogues are related to endogenous, rather than exogenous, signals. Even though the plasma glucose levels after an overnight fast are low (80–100 mg/dL), they maintain the basal insulin secretion *in vivo*,⁹⁰ perhaps by potentiating the insulin response to the low levels of other secretagogues. Recent data suggest that the elevated levels of plasma free fatty acids seen during fasting also help maintain basal insulin secretion.^{91,92} The definition of basal insulin secretion *in vitro* is somewhat arbitrary because it is dependent on the insulin secretagogues present in the buffer. These secretagogues are mandatory; *in vitro* insulin secretion stops in their absence.

Although many investigators assume that basal insulin secretion is constant, others have provided evidence for periodic oscillations in the basal insulin level with periods of 9–14 minutes.^{45,93} The first report of large oscillations in peripheral plasma insulin was from studies in rhesus monkeys;⁹⁴ smaller oscillations were later found in humans.⁹⁵ Oscillations in plasma levels of secretagogues are not the stimulus for the periodicity of basal insulin secretion; the same phenomenon can be demonstrated *in vitro* when secretagogue levels are held constant.⁹⁶ The synchronization of the pancreatic β cell apparently involves intrapancreatic ganglia and nerves, because the oscillations can be reduced by either nicotinic antagonists or neurotoxins.^{97,98} These oscillations in plasma insulin are perturbed in T2DM,^{99,100} and can be partially restored by inhibiting the β cell for a period.¹⁰¹

Secretagogues and Inhibitors of Insulin Secretion

Metabolites

Glucose

Although many agents stimulate insulin release, glucose is the most critical for three reasons (Table 4-1). First, insulin is the major controller of carbohydrate metabolism. For example, during fasting the low levels of glucose (80–100 mg/dL) reduce the plasma insulin level to between 5 and 10 μ U/mL, allowing glycogenolysis, proteolysis, and lipolysis to release stored fuels into the circulation. Conversely, during feeding, the high level of glucose (100–200 mg/dL) increases the plasma insulin level to 30–150 μ U/mL, which not only inhibits the release of stored fuels but also increases the tissue uptake and storage of incoming nutrients. Second, physiologic levels of glucose stimulate insulin release through most of its physiologic range. Thus, changes of plasma glucose level must be taken into account when interpreting insulin secretion. Even the low levels of glucose present during fasting maintain insulin secretion. Third, because glucose plays a central role in β -cell metabolism, glucose can influence the insulin

parameters, such as the acute insulin response (AIR) to glucose, the slope of glycemic potentiation, AIR_{max} , and PG_{50} (discussed later), do relate the insulin responses to the ambient glucose and therefore provide better insight into the function of the pancreatic β cell. The use and limitation of each is discussed below.

Fasting Glucose Levels

The concentration of glucose in the plasma is a very insensitive indicator of β -cell function. A loss of two-thirds of the β cells induced by streptozotocin produces no significant change of the fasting glucose (Table 4-2). Conversely, the increase in obesity does not lower fasting glucose. β -cell dysfunction is severe (total β -cell mass is reduced by 50% or more) when insulin secretion is decreased to 25% of normal.

TABLE 4-2. Indices of Insulin Secretion

INSULIN RESPONSE	Effect	Physiologic State
Experimental	↑↑↑	Carbohydrate feeding
Control (fasting)	↑↑	Protein feeding
Nicotinic acid	0	Fasting
Natural	↑↑	Carbohydrate or Protein meal (?)
Glucose	↑↑	Carbohydrate meal
	↓	Stress
	↓	Feeding
	↓	Feeding (?)
	↓	Stress
	↓	Stress (?)

Early studies suggested that acute increases of triglycerides, free fatty acids (FFAs), and ketones had negligible effects on insulin release in humans. The carbohydrate and protein components of the mixed meal help to stimulate insulin release, which suppresses both lipolysis and FFA mobilization, favoring net storage of ingested triglycerides for the next period of fasting. However, ingested fats slow the absorption of other nutrients that directly stimulate the β cell, such as protein and carbohydrate. Thus mixed meals of varying fat content are not ideal for assessing β -cell function.

More recent studies have revealed both stimulatory and inhibitory effects of FFAs and islet triglycerides on insulin secretion.⁷³ One stimulatory effect of FFAs is to maintain basal insulin secretion during starvation, when plasma glucose levels are very low.⁹² Another stimulatory effect of plasma FFAs is the partial mediation of the increased basal insulin secretion seen in obesity and other insulin-resistant states.^{91,103} In contrast, several *in vitro*¹⁰⁴⁻¹⁰⁶ and *in vivo* studies¹⁰⁷ suggest that chronic, pathologic elevations of plasma FFAs may contribute to impaired insulin secretion, a phenomenon called lipotoxicity.¹⁰⁸ Certain studies have focused on the accumulation of islet triglycerides as critical for lipotoxicity.¹⁰⁸ This lipotoxicity can extend beyond the inhibition of insulin secretion to include inhibition of insulin biosynthesis^{104,109} and the death of susceptible β cells,^{106,108} perhaps mediated by islet triglyceride-dependent generation of nitric oxide (NO),¹¹⁰ a mechanism thought to be involved in the death of islet β cells in type 1 diabetes mellitus (T1DM).

Gastric Inhibitory Polypeptide

Gastric inhibitory polypeptide (GIP) is a 43-amino-acid polypeptide isolated from endocrine cells of the duodenum and jejunum with the ability to inhibit gastric acid secretion. GIP is the few gut hormones released by carbohydrate ingestion. Its release (1) is triggered by intraluminal carbohydrate, not circulating glucose, (2) proportional to the oral glucose load,¹¹¹ and (3) dependent on the absorption of glucose across the intestinal mucosa. These findings suggest that the release of GIP is triggered by stimulation of a glucose sensor within the intestine. Many gut hormones, including GIP, are released by fat and protein ingestion. The effectiveness of GIP to stimulate insulin release is dependent on plasma glucose level (it has thus been renamed glucose-dependent insulinotropic polypeptide [GIP]). Therefore, fat-stimulated GIP release causes little rise of plasma insulin, whereas carbohydrate-stimulated GIP release causes significant insulin release, more than that produced by equivalent levels of glucose alone. Infusions of human form of GIP that reproduce GIP levels during a mixed meal clearly stimulate insulin release.¹¹² Antibodies that bind and neutralize GIP attenuate, but do not abolish, the insulin response to glucose, both supporting a physiologic role for GIP as an incretin and indicating that other factors also participate in the incretin effect. A physiologic incretin effect of GIP is also suggested by studies showing that GIP antagonists attenuate meal-induced insulin release in rats¹¹³ and that mice with gene deletion of the GIP receptor have impaired insulin responses to oral glucose.¹¹⁴

Cholecystokinin

Cholecystokinin (CCK) is a 33-amino-acid peptide released from the duodenum and proximal jejunum with the ability to stimulate insulin release.

TABLE 4-1. Major Secretagogues and Inhibitors of Insulin Release

Secretagogue/Inhibitor	Type	Circulating Concentrations	Effect	Physiologic State
Glucose	Metabolite	5–20 mmol	↑↑↑	Carbohydrate feeding
Amino acids	Metabolite	0.1–10 mmol	↑↑	Protein feeding
Free fatty acids	Metabolite	100–1000 μ mol	0	Fasting
GIP	GI hormone	10 ¹ –10 ² pmol	↑↑	Carbohydrate or fat meal
CCK	GI hormone	1–10 ¹ pmol	↑	Protein meal (?)
GLP-1(7–36)-NH ₂	GI hormone	10 ¹ –10 ² pmol	↑↑	Carbohydrate meal
Epinephrine	Stress hormone	0.2–20 nmol	↓↓	Stress
Neurotransmitters		Synaptic concentrations*		
Acetylcholine	Parasympathetic neurotransmitter	Unknown	↑↑	Feeding
VIP	Parasympathetic neurotransmitter	Unknown	↑	Feeding (?)
Norepinephrine	Sympathetic neurotransmitter	Unknown	↓	Stress
Galanin	Sympathetic neurotransmitter	Unknown	↓↓	Stress (?)

*Neurotransmitters are released locally, achieving concentrations at the β cell that are not currently measurable.

responses to other secretagogues and to subsequent stimulation. Part of the potentiating effects of glucose may be mediated by its effect of increasing insulin synthesis. Thus glucose has a permissive as well as a regulatory role for insulin secretion.

Amino Acids

Most amino acids can stimulate insulin release, but their potencies vary with species, ambient glucose level, and amino acid type. The mixed amino acids in a pure protein meal stimulate insulin release, but less potently than a pure carbohydrate meal. The insulin released during protein meals promotes the uptake and storage of amino acids as muscle protein and slows muscle proteolysis, which supplies gluconeogenic amino acids during fasting. Amino acids stimulate glucagon release, which counteracts the hypoglycemic action of the secreted insulin.¹⁰²

Fats

Early studies suggested that acute increases of triglycerides, free fatty acids (FFAs), and ketones had negligible effects on insulin release in humans. The carbohydrate and protein components of the mixed meal help to stimulate insulin release, which suppresses both lipolysis and FFA mobilization, favoring net storage of ingested triglycerides for the next period of fasting. However, ingested fats slow the absorption of other nutrients that directly stimulate the β cell, such as protein and carbohydrate. Thus mixed meals of varying fat content are not ideal for assessing β -cell function.

More recent studies have revealed both stimulatory and inhibitory effects of FFAs and islet triglycerides on insulin secretion.⁷³ One stimulatory effect of FFAs is to maintain basal insulin secretion during starvation, when plasma glucose levels are very low.⁹² Another stimulatory effect of plasma FFAs is the partial mediation of the increased basal insulin secretion seen in obesity and other insulin-resistant states.^{91,103} In contrast, several *in vitro*^{104–106} and *in vivo* studies¹⁰⁷ suggest that chronic, pathologic elevations of plasma FFAs may contribute to impaired insulin secretion, a phenomenon called lipotoxicity.¹⁰⁸ Certain studies have focused on the accumulation of islet triglycerides as critical for lipotoxicity.¹⁰⁸ This lipotoxicity can extend beyond the inhibition of insulin secretion to include inhibition of insulin biosynthesis^{104,109} and the death of susceptible β cells,^{106,108} perhaps mediated by islet triglyceride-dependent generation of nitric oxide (NO),¹¹⁰ a mechanism thought to be involved in the death of islet β cells in type 1 diabetes mellitus (T1DM).

Hormones

Gastrointestinal Hormones

A variety of gastrointestinal hormones are released during meals to coordinate gastric emptying, gastrointestinal motility, exocrine pancreatic secretion, and gallbladder contraction. These gastrointestinal hormones also potentiate substrate-induced insulin release. The hormones responsible for the extra insulin released by the oral versus intravenous administration of glucose have been termed incretins. Of the many gut hormones evaluated as candidate incretins, the three detailed below have received the strongest support (see Chap. 6).

Gastric Inhibitory Polypeptide

Gastric inhibitory polypeptide (GIP) is a 43-amino-acid polypeptide isolated from endocrine cells of the duodenum and jejunum with the ability to inhibit gastric acid secretion. GIP is one of the few gut hormones released by carbohydrate ingestion. This release (1) is triggered by intraluminal carbohydrate, not circulating glucose, (2) proportional to the oral glucose load,¹¹¹ and (3) dependent on the absorption of glucose across the intestinal mucosa.¹¹¹ These findings suggest that the release of GIP is triggered by the activation of a glucose sensor within the intestine. Many gut hormones, including GIP, are released by fat and protein ingestion. The effectiveness of GIP to stimulate insulin release is dependent on the plasma glucose level (it has thus been renamed glucose-dependent insulinotropic polypeptide [GIP]). Therefore, fat-stimulated GIP release causes little rise of plasma insulin, whereas carbohydrate-stimulated GIP release causes significant insulin release, more than that produced by equivalent levels of glucose alone. Infusions of the human form of GIP that reproduce GIP levels during a mixed meal clearly stimulate insulin release.¹¹² Antibodies that bind and neutralize GIP attenuate, but do not abolish, the insulin response to oral glucose, both supporting a physiologic role for GIP as an incretin and indicating that other factors also participate in the incretin effect. A physiologic incretin effect of GIP is also suggested by studies showing that GIP antagonists attenuate meal-induced insulin release in rats¹¹³ and that mice with gene deletion of the GIP receptor have impaired insulin responses to oral glucose.¹¹⁴

Cholecystokinin

Cholecystokinin (CCK) is a 33-amino-acid peptide isolated from the duodenum and proximal jejunum with the ability to

contract the gallbladder. A much shorter but equally potent form, CCK-8, is found in the nerves of both gut and brain. Both CCKs can stimulate the secretion of digestive enzymes and metabolic hormones such as insulin, as well as inhibit food intake and delay gastric emptying.¹¹⁵ These actions coordinate the flow and processing of nutrients. CCK is released in response to the ingestion of fat and protein, but not carbohydrates.¹¹⁶ Evidence in favor of an incretin action of CCK includes the presence of CCK_A receptors on islet β cells and the finding that the levels of CCK achieved during mixed meals appear sufficient to potentiate amino acid-stimulated insulin release. However, potent antagonists of the CCK_A receptor have little effect upon meal-stimulated insulin release in humans, calling into question a major role for CCK as an incretin.

GLP-1[7-36 Amide]

L cells of the distal small intestine release a peptide encoded by the preproglucagon gene. This peptide is a truncated, amidated form of glucagon-like peptide 1, GLP-1[7-36 amide].¹¹⁷ The plasma concentration of this peptide increases during mixed and carbohydrate¹¹⁸ meals in humans. Although the quantities released are less than those of GIP, GLP-1[7-36 amide] is such a potent glucose-sensitive potentiator of insulin secretion¹¹⁹ that it is currently thought to be a major incretin. Direct experimental support for this concept comes from studies showing that GLP-1 antagonists or immunoneutralization of GLP-1 impairs oral glucose tolerance in primates.¹²⁰ Likewise, transgenic male mice with a knockout of the GLP-1 receptor have both impaired insulin secretion to oral glucose and impaired glucose tolerance.¹²¹ In addition to the incretin effect, evidence is accumulating that GLP-1 helps maintain the normal levels of insulin content¹²² and β -cell mass,¹²³ which are important for insulin responses to other nonincretin stimuli. These latter observations have prompted studies of GLP-1 or analogs for treatment of T2DM.^{124,125}

Gut Neuropeptides

Although the polypeptides discussed above are gastrointestinal hormones, there are many others in the gastrointestinal tract that are localized to nerves, not endocrine cells. Examples are vasoactive intestinal polypeptide (VIP) and the related peptide, pituitary adenylate cyclase-activating peptide (PACAP). Because part of the incretin effect may be mediated by the complex neural activation of the gastrointestinal tract that accompanies meals, it is possible that some of these gut neuropeptides may also serve an incretin function. Indeed, transgenic mice with a knockout of the PACAP 1 receptor have impaired insulin responses to gastric glucose.¹²⁶ Further, recent work suggests that nerves in the myenteric plexus of the adjacent duodenum innervate intrapancreatic ganglia,^{127,128} raising the possibility that the intrapancreatic ganglia may be part of the enteric nervous system of the gut, and as such may be activated during feeding.

Stress Hormones

Epinephrine

The sympathetic neurohormone epinephrine is secreted from the adrenal medulla in response to stress. Such stresses include physical disturbances of homeostasis such as hypoglycemia, hypotension, and hypoxia, as well as the accompanying or preceding emotional responses of fear and/or anxiety. The epinephrine released during stress activates an α_2 -adrenergic inhibitory receptor as well as a β -adrenergic stimulatory receptor on the β cell. This

simultaneous activation results in little net change of basal insulin release, yet substantial inhibition of the acute insulin response to glucose (see Chap. 8).

Others

The pituitary hormones ACTH, growth hormone, TSH, prolactin, and vasopressin and the adrenal and thyroid hormones cortisol and thyroxine, are also released under stress. These hormones are not major, acute modulators of insulin release, although growth hormone and cortisol have long-term direct or indirect effects on insulin secretion in the hours or days following a major stressful event.¹²⁹

Neurotransmitters

Parasympathetic

Acetylcholine (ACh) is the classic postganglionic neurotransmitter of parasympathetic nerves, including those that innervate the pancreas. ACh stimulates insulin release via the M3 subtype of the muscarinic receptor¹³⁰⁻¹³² that can be blocked by atropine. Activation of the parasympathetic nerves of the pancreas can be produced (1) experimentally by electrical activation of the vagus nerve, (2) physiologically by both the cephalic and intestinal phases of feeding, and (3) pathophysiologically by hypoglycemia. The action of ACh to stimulate insulin release is glucose dependent,¹³³ so that during hypoglycemic stress the vagal activation produces little stimulation of insulin release. In contrast, during carbohydrate feeding, equivalent vagal activation would be expected to produce significant neurally induced stimulation of insulin secretion. Old evidence, primarily in rats,¹³⁴ and newer evidence in humans¹³⁵ suggest that pancreatic parasympathetic nerves mediate the cephalic phase of insulin release. This phase occurs before the absorption of ingested glucose. More recent data suggest that pancreatic parasympathetic nerves may also be important for the insulin response during absorption,^{136,137} contrary to the traditional view that ingested metabolites are the primary stimuli for absorptive insulin secretion.

Parasympathetic nerves in the pancreas may also release neuropeptides such as VIP and PACAP. Both have been found in postganglionic parasympathetic-like fibers innervating pancreatic islets, and VIP has been measured in the pancreatic venous effluent during electrical activation of the vagus.¹³⁸ Infusion of exogenous VIP¹³⁸ stimulates glucagon and insulin secretion as well as increasing pancreatic blood flow and the flow of pancreatic exocrine juice.

Sympathetic

Norepinephrine is the classic postganglionic neurotransmitter for the sympathetic neurons that innervate the pancreas. Norepinephrine, like epinephrine, is a dual agonist activating both α_2 -adrenergic inhibitory receptors and β -adrenergic stimulatory receptors on the β cell. The net effect of norepinephrine on insulin secretion *in vivo* is usually inhibition of glucose-stimulated insulin release with little change of basal insulin release. Intrapancratic norepinephrine can be released experimentally by electrical activation of sympathetic nerves and pathophysiologically by hypoglycemic stress.¹³⁹

Sympathetic nerves in the pancreas may also release other neurotransmitters such as neuropeptide Y (NPY) and galanin. NPY fibers innervate the islets of many species, whereas the sympathetic galaninergic innervation of the islet¹⁴⁰ seems restricted to the dog.¹⁴¹ In the dog, but not the primate, galanin is released into the pancreatic venous blood during electrical activation of sympathetic

nerves,^{142,143} and infusion of exogenous galanin impairs both basal and stimulated insulin release.^{140,144} NPY has minor effects on insulin secretion but may stimulate glucagon secretion.¹⁴⁵

Intraislet Peptides

Older evidence suggests an interaction between the different islet cell types. For example, the δ -cell peptide somatostatin may be a paracrine controller of glucagon release.¹⁴⁶ However, evidence of its role as a paracrine controller of insulin release is less well established. Likewise, insulin appears to be a local endocrine controller of glucagon release¹⁴⁷ via the portal circulation from the β -cell core to the α -cell mantle of the normal islet.¹⁴⁸ However, glucagon does not appear to be a physiologic modulator of insulin release within the islet. β cells make and release islet amyloid polypeptide (IAPP) in addition to insulin. Although the physiologic role of IAPP remains unclear, a pathophysiologic role for this peptide has been suggested in type 2 diabetes,^{13,149} since amyloid fibrils are cytotoxic to β cells¹⁵⁰ (see Chap. 21).

Effects of Glucose on Insulin Secretion

Although glucose clearly stimulates insulin release, the simplicity of that statement belies the complexity of glucose's direct effects on insulin secretion and the dominant role that glucose plays in controlling the β -cell response to other secretagogues, both of which are detailed below.

First- and Second-Phase Insulin Release

The magnitude of the insulin response to glucose is related not only to the absolute level of glucose, but also to the rate of change of glucose level. Thus an abrupt increase of glucose level elicits a rapid and transient burst of insulin secretion, called the first or acute phase of insulin response, that subsides within 10 minutes (Fig. 4-2). The second-phase response begins when glucose levels increase slowly and progressively for up to 4 hours of glucose exposure. The separation of these two phases of insulin release has been demonstrated most clearly by exposing the isolated rat pancreas to a large stepwise increase of glucose, but it can also be demonstrated in humans during hyperglycemic glucose clamp studies.

The first-phase insulin response to glucose is not prevented by blockade of insulin synthesis *in vitro*, nor is its magnitude dependent on the prestimulus glucose level *in vivo*. This acute release of insulin may be due to release of insulin granules that are directly adjacent or "marginated" to the β -cell membrane. In contrast, the

magnitude and timing of the second-phase insulin response are dependent upon the prestimulus glucose level *in vivo*. The second-phase response is probably due to the release of more internal insulin granules as well as some that are not preformed, because at least part of this second-phase response is dependent on the synthesis of new insulin. This newly synthesized insulin is preferentially released during the period of continuous glucose stimulation phenomenon observed during stimulation of many other granule secretory processes.

Although these two distinct phases of insulin release do occur in humans following intravenous glucose administration, they are not readily apparent during a carbohydrate meal. During a carbohydrate meal, absorption of glucose into the circulation is not fast enough to produce a rapid increase in the plasma glucose level. However, the rate sensitivity that characterizes the first-phase insulin response to glucose is probably physiologically important even during less abrupt changes of plasma glucose. For example, feedback-controlled insulin infusion studies suggest that a rapid response of the β cell to an increasing plasma glucose level is necessary to prevent excessive hyperglycemia during a carbohydrate meal, as well as to prevent the development of hypoglycemia following the meal¹⁵¹ due to the late and excessive release of insulin and its relatively long duration of action. Recent studies have emphasized the importance of the early insulin response to meals in the preservation of normal glucose tolerance. Thus prevention of this early insulin response in healthy humans results in glucose intolerance,¹⁵² and impairment of this insulin response is associated with glucose intolerance both in individuals at high risk¹⁵³ and those individuals who already have¹⁵⁴ T2DM. The addition of the cephalic phase of insulin response improves the glucose intolerance seen during intragastric installation of glucose in healthy subjects,¹⁵⁵ and infusion of rapid-acting insulin early during the meal corrects the glucose intolerance seen in type 2 diabetes.¹⁵⁶

Potentialiation

Glucose not only stimulates insulin secretion directly, but also influences the magnitude of the insulin response to other, nonglucose, secretagogues. Thus the acute insulin response to gut hormones, amino acids, and other secretagogues is larger when the ambient glucose level is higher (Fig. 4-3). Although the intracellular signals that subserve potentiation are not clear, it is likely that constant stimulation by glucose increases not only the synthesis of new insulin, but also the transport of insulin granules toward the cell membrane, making them available for acute release.

FIGURE 4-2. First- and second-phase response to glucose. Immediately after the stepwise increase of perfusate glucose concentration (300 mg/dL; **first shaded area**), there is a transient burst of insulin release (first phase), which can persist for 2–5 minutes *in vitro*. Thereafter, there is a slow but progressive increase of insulin secretion (second phase), which continues for the duration of the original exposure to the high glucose level (5–52 minutes). **Priming:** Prior exposure (2–52 minutes) of the pancreas to glucose (300 mg/dL, **first shaded area**) produces a first-phase insulin response (57–59 minutes) to an equivalent stepwise increase of glucose (300 mg/dL, **second shaded area**) that is significantly enhanced. FIGURE 4-3. Potentiation: The effect of increasing the ambient glucose level on the magnitude of acute insulin response (AIR) to isoproterenol. (Reprinted with permission from Halter, et al.¹⁵⁷)

secretagogues other than glucose. This potentiating effect has not only been demonstrated *in vitro* using pharmacologic amounts of nonglucose secretagogues, but it is also an important physiologic mechanism for the control of insulin release *in vivo*. For example, the amino acids absorbed during a mixed protein/carbohydrate meal stimulate more insulin secretion because the glucose level is elevated by the digestion and absorption of the carbohydrate. Further, in research settings, the measurement of glucose's ability to potentiate non-glucose-induced secretion has provided clear evidence of defects in β -cell function in T2DM¹⁵⁷ (see Chap. 21).

Priming

In addition to directly stimulating and potentiating insulin secretion, glucose also has a priming effect on the β cell. That is, previous exposure to high levels of glucose can enhance the insulin response to subsequent stimulation even though the glucose levels have returned to normal (Fig. 4-2). Thus the β cell's acute response to glucose or other secretagogues is conditioned by its "memory" of prior glucose stimulation. The amount of subsequent priming is increased with the magnitude and duration of the original glucose exposure; it is decreased by lengthening the time between the end of that exposure and subsequent stimulation.¹⁵⁸ The priming effect is not dependent upon the original insulin secretion itself, because blockade of that insulin release still permits priming of subsequent insulin responses.¹⁵⁸ The priming effect is apparently dependent on intracellular glucose metabolism, because some glycolytic intermediates can also produce priming. Because prior exposure to glucose also increases the subsequent acute insulin response to arginine in humans, the priming effect probably increases the slope of glycemic potentiation. Priming may also account for the dramatic differences in the insulin responsiveness between fasted and recently fed individuals, and probably contributes to the effects of antecedent diet on the insulin response to an oral glucose tolerance test (see below).

Desensitization

Chronic exposure of the β cells to high glucose levels ultimately leads to a decrease in the sensitivity of the β cells to stimulation by glucose. *In vitro* this desensitization appears after 4–8 hours of exposure, when insulin secretion is decreased to 25% of maximal.¹⁵⁹ Desensitization may be due to a downregulation of the glycolytic enzymes within the β cell, but this is not the only mechanism, because chronic exposure of β cells to nonglucose stimuli also produces desensitization. Likewise, the reduced insulin secretion is not due to a significant reduction of total insulin content or to a decrease in the rate of insulin synthesis.¹⁵⁹ Desensitization may, however, be related to depletion of insulin from a very responsive subset of β cells, leaving insulin to be secreted from progressively fewer responsive β cells. Indeed studies suggest the presence of sets of β cells within the islet that have different thresholds and sensitivities for stimulation by glucose.¹⁶⁰ There is also evidence of early hypersensitivity of the β cell to glucose stimulation, perhaps mediated by increases of glucokinase activity. Such increased glucokinase activity may produce overstimulation of β cells despite modest hyperglycemia, and therefore result in a later loss of glucose responsiveness.

Desensitization can also occur *in vivo* after exposure to either 2 days of marked hyperglycemia in normal rats or 6 weeks of minimal hyperglycemia in partially pancreatectomized rats.¹⁶¹ After such exposure, the first-phase insulin response to glucose in the subsequently isolated and perfused pancreas is nearly abolished. Restoration of euglycemia in partially pancreatectomized rats lessens the impairment of the first-phase insulin response.¹⁶² Even short periods of extremely low glucose *in vitro* can reverse the suppressive effects of long periods of hyperglycemia *in vivo* on the acute insulin response to glucose. Interestingly, such *in vitro* exposure does not reverse the suppressive effect of hyperglycemia on the second phase of the insulin response. Those data suggest that the chronic hyperglycemia present in T2DM may exacerbate the defect in glucose-stimulated insulin secretion.¹⁶³ It is interesting that many type 2 diabetic patients retain some of their second-phase insulin response to glucose; in contrast, this response is almost completely lost in most animal models with chronic hyperglycemia (see Chap. 21).

In Vivo Measures of Insulin Secretion and β -Cell Function

When determining the function of the pancreatic β cell, it is critical to relate the amount of insulin secretion to the amount of glucose stimulation that the β cell receives. For example, if the plasma insulin level has increased appropriately in response to an increase in plasma glucose, then the efficiency or function of the β cell has not really changed. Alternatively, if insulin secretion has increased more than expected for the increase of ambient glucose level, then β -cell function has increased. Several *in vivo* measurements, such as fasting plasma glucose level, oral and intravenous glucose tolerance tests, and fasting insulin level, have been used to suggest changes of β -cell function. However, these measures either do not adequately take into account the insulin level at which the glucose level is measured or, conversely, the ambient glucose level at which the insulin level is measured. Although they may reveal some information either about the amount of insulin released or its effect on plasma glucose, they may not provide reliable information about how efficiently the pancreatic β cell reacts to glucose as a stimulus—that is, β -cell function. Other measures or calculated

parameters, such as the acute insulin response (AIR) to glucose, the slope of glycemic potentiation, AIR_{max} , and PG_{50} (discussed later), do relate the insulin responses to the ambient glucose level and therefore provide better insight into the function or efficiency of the pancreatic β cell. The use and limitation of each index is discussed below.

Fasting Glucose Levels

The concentration of glucose in the plasma of fasting individuals is a very insensitive indicator of β -cell function. For example, loss of two-thirds of the β cells induced by partial pancreatectomy produces no significant change of the fasting glucose level^{164,165} (Table 4-2). Conversely, the increase of β -cell function that occurs in obesity does *not* lower fasting glucose levels. However, if the β -cell dysfunction is severe (total pancreatectomy or autoimmune

or chemical destruction of most β cells), then fasting hyperglycemia will result. Thus the fasting glucose level reflects only impairments of β -cell function that are severe enough to prevent the increase of insulin secretion that usually compensates for loss of β -cell mass or defects in insulin action.

Oral Glucose Tolerance Test

The insulin released by the ingestion of carbohydrate aids in the clearance of the absorbed glucose from plasma. Thus in the oral glucose tolerance test (OGTT), plasma glucose levels at specific times after a standard oral glucose load (usually 75 g) are used to assess the adequacy of insulin secretion. However, the relationship between the insulin and glucose levels is time-dependent, because the insulin released early in the test influences the glucose value later in the test. Thus only the early part of the OGTT can be used

TABLE 4-2. Indices of Insulin Secretion and β -Cell Function in Normal and Pathophysiologic States

to estimate β -cell function. One such estimate is the insulinogenic index, which is the early increment of plasma insulin divided by the early increment of plasma glucose. This index provides a crude measure of β -cell function useful in epidemiologic studies.¹⁶⁶ However, low insulinogenic values do not necessarily reflect just β -cell defects, since part of the early insulin release is in turn stimulated by activation of the parasympathetic nervous system and the release of gastrointestinal hormones that occurs during digestion. Impairment of gastrointestinal function can therefore influence both the insulinogenic index and the OGTT by reducing gastrointestinal hormone release and by reducing the rate of glucose absorption. Further, the rate of clearance of glucose from plasma is dependent not only on the amount of insulin secreted, but also on the sensitivity of liver and muscle to insulin. Both stress and obesity can produce insulin resistance, resulting in impaired glucose tolerance in the face of a normal or even an enhanced insulin response. Thus the ability of other factors besides insulin secretion to influence the plasma glucose levels during the oral glucose tolerance test makes it difficult, if not impossible, to assess the adequacy of β -cell function. Only when the impairment of glucose tolerance is severe, as in diabetes, can the OGTT be used to infer an impairment of the pancreatic β cell's ability to recognize glucose.¹⁶⁷

Intravenous Glucose Tolerance Test

The rapid intravenous injection of a bolus of glucose (usually 5–25 g) results in a rapid peak of the plasma glucose level (between 2 and 4 minutes) followed by a slower, nearly exponential fall in the plasma glucose level. The rate of the fall during the first 10 minutes of the test is largely influenced by the mixing and distribution of glucose, but the natural logarithm of the rate of the fall between 10 and 30 minutes can be used to define the glucose disappearance constant, K_G , which is related to glucose uptake and is therefore an index of glucose tolerance.

The intravenous glucose tolerance test (IVGTT) avoids some of the previously mentioned problems with the OGTT. Because the glucose is administered intravenously, abnormalities in glucose absorption and gastrointestinal function do not affect plasma glucose levels. Further, activation of the parasympathetic nervous system and release of gastrointestinal hormones do not occur during IV injection of glucose, but only during its oral ingestion. One serious problem remains, however. Changes in the sensitivity of peripheral tissues to the action of secreted insulin do influence the plasma glucose profile during the IVGTT. In fact, an estimate of insulin sensitivity can be obtained from the plasma glucose profile, providing that one adequately accounts for the timing and magnitude of the insulin response.¹⁶⁸ In addition, the rate of glucose fall is dependent on the mass-action effect of glucose to accelerate its own disposal, a factor that may change in pathophysiologic states. Thus, K_G is a combined measure influenced not only by the timing and magnitude of the insulin response to the bolus injection of glucose, but also the sensitivity of tissues to the effects of both glucose and insulin to accelerate glucose uptake. When K_G is 1.7 or greater, neither insulin secretion nor insulin action is likely to be markedly impaired. If K_G is between 1.0 and 1.7, then insulin secretion, insulin action, or both are impaired. Only when K_G is less than 1.0 is a reduction of β -cell function always indicated; however, it is usually already evidenced by fasting hyperglycemia (Table 4-2).

Fasting Insulin Levels

The plasma insulin level in a normal weight, overnight-fasted individual is approximately 5–15 μ U/mL. Insulin action has a clear

effect on this measure of insulin release. The fasting insulin level can be low (for example, 3–5 μ U/mL) in well-trained, lean athletes¹⁶⁹ who are very sensitive to insulin; it can be high (15–40 μ U/mL) in obese subjects who are insulin-resistant (Table 4-2). The fasting plasma glucose level is also a major determinant of fasting insulin levels. For example, fasting insulin levels decrease progressively during 8 days of starvation, despite the insulin resistance associated with starvation, because the plasma glucose levels decrease progressively. In contrast, β -cell mass is usually not a determinant of the fasting insulin level. For example, partial pancreatectomy does not lead to a significant decrease in the fasting insulin level.^{164,165} Likewise, streptozocin can produce significant β -cell damage without lowering the fasting insulin level.¹⁷⁰ Apparently the remaining β cells increase their basal secretory rate to compensate. Moreover, in type 2 diabetes and even in some type 1 diabetic patients, fasting insulin levels can be within the normal range, reflecting adequate basal insulin secretion. However, these “normal” fasting insulin levels present in the diabetic state do not take into account the marked differences in the fasting glucose level between diabetic and normal individuals.^{157,171} When the fasting insulin levels are compared at the matched hyperglycemic levels of diabetes, it becomes apparent that diabetic patients have a major impairment of β -cell function.^{157,171} Thus fasting insulin levels reflect changes in insulin sensitivity and in the fasting plasma glucose level, but do not usually reflect reductions in β -cell mass or β -cell function. Some insight into β -cell function can be derived from the combination of fasting insulin and glucose values when interpreted in the context of insulin sensitivity.¹⁷²

First-Phase Insulin Response to Glucose

The acute or first-phase insulin response to glucose is a large and transient increase of the plasma insulin level. The acute response can be elicited by either an intravenous bolus of glucose like that used for the IVGTT or the rapid rise of glucose that occurs at the start of a hyperglycemic clamp.¹⁷³ Even though glucose levels remain elevated during the hyperglycemic clamp, insulin levels fall, reaching a nadir at 10 minutes, which defines the end of the first phase.¹⁷⁴ The magnitude of this acute insulin response (AIR) to glucose, unlike most other insulin responses, is *independent* of the prestimulus glucose level *in vivo*. This feature allows comparison of insulin responses without the need to experimentally match the basal glucose levels between groups. For example, the β -cell dysfunction present in type 2 diabetes is reflected by the absence of the AIR to glucose (see Chap. 21) despite the presence of fasting hyperglycemia. Less severe β -cell loss or dysfunction that does not produce fasting hyperglycemia, such as two-thirds pancreatectomy or low-dose streptozocin, results in a transient reduction of the AIR to glucose that usually resolves despite continuing β -cell dysfunction.^{164,170} Conversely, changes in insulin sensitivity are usually reflected by changes in the AIR to glucose. Obesity¹⁶⁸ and the accompanying insulin resistance¹⁷⁵ are associated with an enhanced AIR to glucose. In summary, the magnitude of the AIR to glucose is not determined by the prestimulus plasma glucose levels. The changes of the AIR to glucose usually reflect changes in insulin sensitivity and can reflect early reductions in β -cell mass and β -cell function.

Second-Phase Insulin Response to Glucose

Sustained hyperglycemia elicits a second phase of insulin secretion that is dependent on both the glucose level and the duration of the hyperglycemia. Thus quantitation of this second-phase in-

ulin response requires a fixed glucose level like that achieved during the hyperglycemic clamp technique. The second-phase insulin response is usually measured from the nadir following termination of the first phase of the insulin response. During the second-phase response, plasma insulin levels increase linearly with time for at least 2 hours.¹⁷⁴ The magnitude of the second-phase insulin response is also influenced by the prestimulus glucose level, like many other insulin responses, and therefore is less useful than the first-phase response in comparing β -cell function between groups with differing fasting glucose levels.

Acute Insulin Response to Nonglucose Stimuli

The magnitude of AIR to nonglucose stimuli such as amino acids, neurotransmitters, and gut hormones is dependent on the prestimulus glucose level. As the glucose level is raised from 100 to 250 mg/dL, the AIR increases in an almost linear fashion (Figs. 4-3 and 4-4). The slope of the straight line relating the magnitude of AIR to the ambient plasma glucose level at which it was measured is defined as the *slope of glycemic potentiation*. As the plasma glucose level is increased above 250 mg/dL, the relationship between AIR and the plasma glucose level is no longer linear, exhibiting a progressively decreasing slope as the glucose levels approach 450 mg/dL. Above 450 mg/dL, there is usually no further increase in AIR. This maximal acute insulin response (AIR_{max}) is a critical parameter for characterizing this curve and thus β -cell function (see below). Because a standard Michaelis-Menten equation does not fit this curve, one cannot calculate the analogous

value of K_m . However, an alternative parameter, the glucose level giving a half-maximal response (PG_{50}), provides an estimate of β -cell sensitivity to glucose (see below).

Slope of Glycemic Potentiation

The slope of glycemic potentiation has been used as an index β -cell function. However, a decrease in slope could be due to either of two causes: a decrease in the overall capacity of the pancreas to secrete insulin, or a decrease in the sensitivity of the individual β cells to respond to the potentiating effects of glucose. For example, partial pancreatectomy, which by definition decreases overall β cell mass and thus the maximal capacity of the pancreas to secrete insulin, also decreases the slope of glycemic potentiation, despite evidence that the glucose sensitivity of the remaining β cells is increased, not decreased.¹⁶⁴ Conversely, treatment with an insulin inhibitory analog of somatostatin, octreotide (SMS-201,995) which decreases the sensitivity of the β cell to glucose, markedly reduces the slope of potentiation despite evidence that the maximal capacity of the β cell to secrete insulin is not decreased. The important point is that although the slope of glycemic potentiation can be a useful measure of β -cell function, it is a combined measure that is influenced by both changes in insulin secretory capacity and by changes in sensitivity of the β cell to the potentiating effects of glucose. To determine which of these two factors is responsible for the changes in slope, one must complete the dose-response curve and from it calculate the parameters AIR_{max} and PG_{50} .

AIR_{max}

The ability of glucose to potentiate the acute insulin response to nonglucose stimuli is limited. In normal humans it is maximal at a glucose level of approximately 450 mg/dL (Fig. 4-4). This maximal acute insulin response (AIR_{max}) is a measure of the insulin secretory capacity of the pancreas. AIR_{max} is a very sensitive indicator of β -cell loss, damage, or dysfunction. Thus, AIR_{max} is markedly reduced in type 2 diabetic patients¹⁷⁶ and even in nonhyperglycemic animals with two-thirds pancreatectomy (Table 4-2).¹⁶⁴ Conversely AIR_{max} is increased, but to a smaller extent, in states of increased β -cell function such as experimentally induced insulin resistance.¹⁷

PG_{50}

β -Cell sensitivity to the potentiating effects of glucose can be estimated by the parameter PG_{50} , which is calculated from the dose-response curve relating AIR to nonglucose stimuli to the plasma glucose level. This dose-response curve must include the maximal acute insulin response to a nonglucose stimulus, because PG_{50} is defined as the ambient glucose level at which the half maximal AIR response occurs (Fig. 4-4). Although PG_{50} , as opposed to the slope of glycemic potentiation, is an index of the sensitivity of the individual β cells to the potentiating effects of glucose, PG_{50} and glucose sensitivity are inversely related. Thus, if the calculated PG_{50} increases, then the sensitivity of the β cells to the potentiating effects of glucose has decreased. Further, because the calculation of this parameter, as opposed to slope of glycemic potentiation, involves normalization to the AIR_{max} , PG_{50} provides an index of sensitivity that is independent of changes in the overall capacity of the pancreas to secrete insulin. For example, partial pancreatectomy, which markedly reduces β -cell mass and thus AIR_{max} , decreases PG_{50} ,¹⁶⁴ reflecting an actual increase in the sensitivity of the remaining β cells to the potentiating effects of glucose. Conversely, treatment with a somatostatin analog that does not decrease AIR_{max} produces a significant increase of PG_{50} , indicating

FIGURE 4-4. Relationship between magnitude of acute insulin response (AIR) to arginine and the prestimulus glucose level in normal human subjects, illustrating calculation of the slope of glycemic potentiation, AIR_{max} , and PG_{50} . (Reprinted with permission from Ward, et al.¹⁷⁶)

a marked decrease in the sensitivity of the β cell to the potentiating defects of glucose. Finally, type 2 diabetic patients who have a marked reduction in AIR_{max} , due presumably to a combination of β -cell loss and β -cell dysfunction, have a normal PG_{50} , suggesting that the residual functioning β cells are normally sensitive to the potentiating effects of glucose.¹⁷⁶

Proinsulin: Insulin Ratio

In the normally functioning β cell, the vast majority (>95%) of proinsulin is converted to insulin and C peptide before release. However, in certain states this conversion is less complete, resulting in both greater pancreatic content and increased circulating levels of proinsulin relative to insulin. In practice, insulin is usually measured with radioimmunoassays using antibodies that cross-react with proinsulin and its degradation intermediates. Thus, immunoreactive insulin (IRI) can be a measure of the combination of insulin and proinsulin-like molecules; selective antibodies or special separation techniques are required to measure proinsulin by itself in order to calculate a PI:IRI ratio. This PI:IRI ratio is the percentage of all molecules containing insulin that are comprised of true proinsulin. The PI:IRI in extracts of the pancreas is less than 5%. Presumably, most of the proinsulin and insulin are already in releasable β -cell granules, because the PI:IRI ratio in plasma after acute stimulation of the β cell is similar.¹⁷⁷ In theory, agents that produce other types of acute stimulation or inhibition of the β cell should not change the ratio significantly, because they would be expected to influence the secretion of proinsulin and insulin equally. This concept ignores, however, the plasma clearance of proinsulin, which is markedly slower than that of insulin. This differential clearance accounts for a higher PI:IRI (15%) obtained from the plasma of fasting human subjects.¹⁷⁷ Thus, one should not compare fasting to stimulated PI:IRI ratios to infer a change of the β -cell function.

The effect of drugs and physiologic or pathophysiologic states on the fasting PI:IRI in plasma has been used to infer changes of the intracellular processing of insulin and, therefore, of β -cell function; decreased PI:IRI is interpreted as more efficient β -cell

function, whereas increased PI:IRI is interpreted as impaired β -cell function. This interpretation is supported by several pieces of experimental evidence. First, drugs that impair β -cell function, such as glucocorticoids^{171,177} and streptozocin,¹⁷⁸ increase the plasma PI:IRI. Second, type 2 diabetic patients who have other evidence of β -cell impairment have increased PI:IRI.¹⁷⁷ Increases of PI:IRI do not appear to be secondary to the increased secretory demand on a normal β cell because partial pancreatectomy, obesity, and drug-induced insulin resistance, all of which increase secretory demand, do not increase the PI:IRI ratio. However, increased demand on an already impaired β cell may increase the PI:IRI ratio simply by accelerating proinsulin release before full processing can occur.¹⁷⁹ Thus an increased PI:IRI has been used to suggest impaired β -cell function in individuals at high risk for development of type 2 diabetes.¹⁸⁰

Adaptive Changes of Insulin Secretion

β -Cell Adaptation to Insulin Resistance

Introduction

Resistance to the action of secreted insulin leads to a compensatory increase of insulin release. When β cells are functioning normally, the extra insulin released is usually sufficient to overcome the resistance to insulin's action and to prevent marked fasting hyperglycemia and glucose intolerance. The normal relationship between insulin secretion and insulin action is hyperbolic^{181,182} (Fig. 4-5), implying that their product is a constant called the disposition index.¹⁸¹ Changes in insulin secretion that fully compensate for changes in insulin resistance result in movement along this hyperbolic line and maintenance of glucose tolerance. Therefore, this hyperbolic function has been called an isotolerance line.¹⁸² Only when the insulin resistance is extreme (as in congenital receptor loss with acanthosis nigricans) or when the capacity of the β cell to secrete insulin is severely impaired (as in type 2 diabetes) does insulin resistance result in fasting hyperglycemia. More modest reductions in insulin secretory capacity

FIGURE 4-5. Hyperbolic relationship between the fasting plasma insulin level and the insulin sensitivity index in normal human subjects. (Reprinted with permission from Kohn, et al.¹⁸²)

result in glucose intolerance without fasting hyperglycemia, a characteristic of groups at high risk for progression to type 2 diabetes. However, in most individuals insulin resistance is accompanied by an increase in several indices of insulin secretion, particularly the fasting plasma insulin level, and is therefore rarely accompanied by fasting hyperglycemia.

Drug-Induced Insulin Resistance

Certain drugs and hormones such as growth hormone, glucocorticoids, and nicotinic acid¹⁸³ can produce a rapid and reversible insulin resistance which is accompanied by a compensatory increase of insulin secretion. However, growth hormone and corticosteroids have direct inhibitory effects on the β cell that prevent complete compensation and thus produce mild hyperglycemia. In contrast, nicotinic acid has minimal direct effects on the β cell and markedly reduces insulin action (Table 4-2).¹⁷⁵ In humans, 2 weeks of treatment with nicotinic acid doubles the fasting insulin level with no change of the fasting plasma glucose level, and nearly doubles the acute insulin response to glucose and nonglucose secretagogues. The slope of glucose potentiation increases slightly as does AIR_{max} , with no change of PG_{50} or $PI:IRI$. Thus, the β cells appear to increase their secretion of insulin by increasing their overall secretory capacity. Perhaps the higher and more prolonged glucose levels during meals, suggested by glucose intolerance, may mediate this increase of AIR_{max} .

Gene-Induced Insulin Resistance

Certain genetic knockouts of the insulin receptor, its signaling molecules, or the insulin-sensitive glucose transporter (GLUT-4) cause insulin resistance and hyperinsulinemia. For example, knocking out the insulin receptor in the liver produces hepatic insulin resistance and hyperinsulinemia, the latter due to both decreased hepatic insulin clearance and increased insulin secretion.¹⁸⁴ Knocking out insulin receptor substrate-1 (IRS-1) produces muscle insulin resistance,^{185,186} hyperinsulinemia,¹⁸⁷ and a β -cell hyperplasia^{188,186} that is also seen in obesity. Knocking out insulin receptor substrate-2 (IRS-2) produces liver insulin resistance¹⁸⁸ and a transient hyperinsulinemia. A heterozygous, global knockout of GLUT-4 causes insulin resistance and hyperinsulinemia.¹⁸⁹ Thus the genetic disruption of certain insulin signaling pathways causes insulin resistance resulting in a compensatory hyperinsulinemia. Indeed, earlier studies of drug-induced insulin resistance had demonstrated this compensatory hyperinsulinemia.¹⁷⁵

Surprisingly, genetic disruption of the insulin signaling pathway selectively in muscle^{190–192} does not cause hyperinsulinemia despite the current view that muscle is quantitatively the most important tissue for insulin-mediated glucose disposal.

Finally, in some knockout mice with insulin resistance, the hyperinsulinemia is transient or does not occur at all because of defects in β -cell function. Thus the transient hyperinsulinemia of IRS-2 knockout mice is followed by diabetes¹⁸⁸ because β -cell hyperplasia, normally seen in response to sustained insulin resistance, is mediated through IRS-2.¹⁹³ Thus knockout mice with defects in both insulin action and β -cell function develop diabetes,^{187,188} whereas those with defects in insulin action alone develop compensatory β -cell hyperplasia and hyperinsulinemia.

Obesity-Related Insulin Resistance

Experimental Obesity Lesions of the ventromedial hypothalamus (VMH) produce obesity and insulin resistance in rats. Their

fasting glucose levels are normal, and their fasting insulin level and AIR are elevated. Although the more sophisticated tests of β function have not been performed in VMH-lesioned animals, AIR to nonglucose secretagogues is also elevated, suggesting that the slope of glycemic potentiation might be increased.

Although the origin of this hyperinsulinemia in VMH-lesioned animals has not been definitively established, three observations suggest that increased parasympathetic tone to the pancreas contributes to this hyperinsulinemia. First, the rise of plasma insulin level immediately following the actual lesioning is rapid enough to be neurally mediated. Second, this acute increase of insulin can be reversed by vagotomy. Third, autotransplantation of the pancreas, which severs extrinsic pancreatic nerves, also lowers the plasma insulin level. It is interesting, however, that part of the hypersecretion persists even when the pancreas is isolated and perfused *in vitro*.¹⁹⁴ This residual hypersecretion can be reversed by atropine, suggesting that intrinsic cholinergic stimulation of insulin secretion is also increased.¹⁹⁵ There is also evidence for increased sympathetic tone to the pancreas in VMH-lesioned animals,¹⁹⁶ which should enhance insulin secretion. Recent studies suggest that increased parasympathetic activity can decrease pancreatic sympathetic tone.¹⁹⁷

Certain strains of mice and rats develop obesity by inheritance of a recessive gene. In *ob/ob* mice there is a defect in the coding for an adipocyte protein,¹⁹⁸ leptin, that has satiety effects in *ob/ob* and wild-type but not *db/db* mice.¹⁹⁹ Zucker (*fa/fa*) rats and other obese rats overexpress the *ob* protein leptin,²⁰⁰ but like *db/db* mice, are resistant to its action because of a defect in the leptin receptor. These mice and rats are also insulin resistant. In the *fa/fa* rats, fasting glucose levels are near normal, but fasting insulin levels and AIR to secretagogues are markedly exaggerated. Although the mechanism for the hyperinsulinemia has not been established, increased vagal tone has been suggested: The animals are hyperresponsive to vagal stimulation and vagotomy partially decreases their hyperinsulinemia.²⁰¹ Zucker fatty (*fa/fa*) rats have decreased pancreatic sympathetic tone,²⁰² as do the VMH-lesioned rats. The decreased pancreatic sympathetic tone may contribute to the hyperinsulinemia.

Obesity can also be induced by high-energy diets in approximately one-half of outbred Sprague Dawley rats; the other half are resistant to this diet-induced obesity (DIO). These DIO rats have increased carcass fat,²⁰³ presumed insulin resistance, and hyperinsulinemia.²⁰³ Rats with DIO have decreased pancreatic sympathetic tone,^{203,204} as do the VMH-lesioned and Zucker fatty rats. This decreased sympathetic tone may contribute to their hyperinsulinemia. The role of pancreatic parasympathetic tone in the hyperinsulinemia of DIO has not been examined.

Both *fa/fa* and VMH-lesioned rats eventually develop enlarged islets, either as a response to chronic parasympathetic stimulation or as a response to the chronic need for increased insulin secretion secondary to their chronic insulin resistance. This hypertrophy may result in increased insulin secretory capacity and thus increase AIR_{max} .

Naturally Occurring Obesity Human obesity is also characterized by insulin resistance.²⁰⁵ The fasting glucose level is normal in the vast majority of obese subjects, but the fasting insulin levels are usually elevated in proportion to the amount of excess body fat and the degree of insulin resistance²⁰⁶ (see Chaps. 21 and 22 and Table 4-2). Drugs such as thiazolidinediones, which reduce insulin resistance, reduce this basal hyperinsulinemia.²⁰⁷ The insulin

responses to acute secretagogues and the slope of glycemic potentiation are increased in obese subjects,²⁰⁸ but the PI:IRI is unchanged (see Fig. 4-6 and Table 4-2).²⁰⁹ Cross-sectional data obtained from human subjects of varying degrees of obesity¹⁸² suggest that AIR_{max} is also increased, consistent with the enlarged islets found during autopsy of obese humans.

Although the mechanism of hyperinsulinemia in human obesity is still being debated, most believe it to be secondary to increased insulin secretion. Such increased secretion may be due to the increased ratio of pancreatic parasympathetic to sympathetic tone discussed above for the rodent models of obesity. Other potential causes include glucose intolerance that can accompany insulin resistance. These prolonged elevations of plasma glucose after meals may prime the β cells, producing an increase in their sensitivity to the potentiating effects of glucose. There is also evidence that plasma FFAs are elevated in the obese subjects and they contribute to the hyperinsulinemia observed in this state.^{91,103} Finally, another potential cause of hyperinsulinemia is related not to insulin secretion, but to the clearance of insulin: In obese humans, the insulin resistance is associated with reduced removal of insulin from plasma.^{206,210,211}

Just as weight gain produces insulin resistance, both long-term weight loss and exercise increase insulin sensitivity. Exercise increases the amount of glucose uptake at a given insulin level, resulting in an increase of whole-body measures of insulin sensitivity. This increased insulin sensitivity persists for a few days after the exercise, but is lost after 2 weeks of relative inactivity.²¹² As a result of this increased sensitivity to insulin's action on glucose disposal and a decrease of the fasting glucose level, insulin secretion decreases.^{169,212} In animals, the decrease of insulin secretion is accompanied by a decrease of proinsulin and glucokinase mRNA, suggesting a decrease in islet glucose metabolism and insulin synthesis.²¹³ In well-trained humans, fasting plasma insulin levels can be very low (3–5 μ U/mL), as is the AIR to glucose¹⁶⁹ or nonglucose secretagogues. As little as a week of exercise training can decrease insulin secretion in the elderly, without any change of weight or body composition. Long-term exercise training in the elderly produces a decrease of AIR_{max} with no change in PG_{50} ,²¹⁴ suggesting that the reduction of insulin secretion in response to exercise may be due to a reduction of insulin secretory capacity.

Adaptation to Partial β -Cell Loss or Dysfunction

Experimental β -Cell Loss or Dysfunction

Partial Pancreatectomy One can remove up to 80% of the pancreas and yet not produce the fasting hyperglycemia characteristic of diabetes. However, 80% suppression of insulin with an insulin-selective analogue of somatostatin does produce marked hyperglycemia.²¹⁵ The combined data imply that after pancreatectomy, the remaining β cells increase their secretion of insulin to compensate for the β -cell loss, whereas during somatostatin analogue infusion, all β cells are inhibited. Indeed, studies demonstrate that two-thirds pancreatectomy in dogs produced no reduction of the fasting insulin level or PI:IRI and only a small reduction of AIR_G .¹⁶⁴ The AIR_{max} was, however, markedly reduced in proportion to the β -cell loss (Fig. 4-7).¹⁶⁴ Interestingly, PG_{50} appeared to be decreased,¹⁶⁴ suggesting that sensitivity of the remaining β cells to the potentiating effects of glucose was enhanced, perhaps accounting for the maintenance of near-normal basal insulin and glucose level. Studies of islets isolated from rats several weeks after 60% pancreatectomy demonstrate the suspected increase in the sensitivity of the remaining β cells to glucose. Although fasting hyperglycemia is

FIGURE 4-7. A. Effect of two-thirds pancreatectomy (px) on the slope of glycemic potentiation and AIR_{max} in dogs. B. Effect of two-thirds pancreatectomy on PG_{50} , an index of β -cell sensitivity to the potentiating effect of glucose. Note that the data in A have been normalized to their respective maximal responses and replotted in B to illustrate the leftward shift in the dose-response curves. (Solid line, animals before px; dashed line, animals 1 and 6 weeks after px.) (Reprinted with permission from Ward, et al.¹⁶⁴)

not required for this increased sensitivity to occur, the mechanism still may involve stimulation of the residual β cells by abnormally elevated glucose levels following meals.

A series of partial pancreatectomy studies in young rats suggests another mechanism for compensatory insulin secretion: regrowth of islets. A 90% pancreatectomy resulted in a tripling of the pancreatic remnant weight and insulin content over the next 2 months.¹⁶⁵ However, the importance of this mechanism of compensation in adult animals remains to be established.

β -Cell Toxins β -Cell toxins such as alloxan and streptozocin have been used extensively to produce animal models of diabetes. The amount of β -cell damage is dose and age dependent. When streptozocin is given to neonatal rats, it produces severe transient hyperglycemia that evolves into a mild persistent hyperglycemia. The pancreata of these animals seem insensitive to the acute stimulatory effects of glucose *in vitro*.²¹⁶ The β cells can mount a small insulin response to arginine, but it is maximal at low levels of glucose.²¹⁶ Thus the dose-response curve is attenuated and shifted to the left, demonstrating a decrease of insulin secretory capacity and suggesting an increase in the sensitivity of the remaining β cells to the potentiating effects of glucose, similar to that seen in partially pancreatectomized animals.

Low doses of streptozocin given to baboons do not increase fasting plasma glucose, decrease fasting plasma insulin,¹⁷⁰ or increase PI:IRI.¹⁷⁸ However, K_G , AIR to glucose and arginine, and the slope of glycemic potentiation all decrease initially (Table 4-2).¹⁷⁰ Two months later, however, most indices return toward normal with the exception of the slope of glycemic potentiation, which remains markedly impaired (Fig. 4-8).¹⁷⁰ Thus the reduced

slope of glycemic potentiation may be an indicator of persistent β -cell damage.¹⁷⁰

Naturally Occurring β -Cell Loss or Dysfunction

Subclinical Type 1 Diabetes The risk of developing type 1 diabetes is 0.1–0.3% in the general population but 10–15% among first-degree relatives of type 1 diabetic individuals. The risk is 20–30% in HLA-identical siblings of type 1 diabetic patients and 30–40% in monozygotic twins of a person with type 1 diabetes.²¹⁷ In addition to the genetic factors that increase the risk of developing type 1 diabetes, there are other factors, such as environmental ones, that increase the risk.

Many of those predisposed to type 1 diabetes have islet dysfunction years before presentation of clinical diabetes, suggesting that the autoimmune process has either reversibly impaired or even destroyed a significant percentage of β cells (see Chap. 20). This islet dysfunction is manifested by a reduced AIR to glucose,²¹⁸ and a relative reduction in the slope of glycemic potentiation and AIR_{max} .²¹⁹ Certain studies suggest that the β -cell destruction can be progressive not only because of continued autoimmune attack on the remaining β cells, but also because of the increasing demand placed on the dwindling number of β cells. This concept has led to attempts to arrest or delay the development of type 1 diabetes by treatment of high-risk subjects either with immune suppressants or with agents that rest the β cell.²²⁰ There are major therapeutic trials in progress to prevent or delay development of type 1 diabetes in high-risk individuals.²²¹ To identify those at high risk for development of this disease, most workers have focused on the detection of autoantibodies generated by antigens released from destroyed β cells. The combination of the standard islet cell antibody²²² with autoantibodies against glutamic acid decarboxylase (GAD-65)²²³ and a newer islet cell antibody (ICA 512) improves the prediction of risk²²⁴ since it increases the association with a markedly decreased AIR_G ²²⁴ (see Chap. 20).

FIGURE 4-8. Effect of subdiabetogenic doses of streptozocin (STZ) on the slope of glycemic potentiation in baboons. Stage 1 (—), normal animals before STZ; stage 2 (---), animals 1 week after STZ; stage 3 (----), animals 5 weeks after STZ. (Reprinted with permission from McCulloch, et al.¹⁷⁰)

Type 1 Diabetes In type 1 diabetes, the β -cell damage is so extensive that there are few β cells left to compensate. The compensation, if present, shows up in some type 1 diabetic patients as fasting plasma insulin or C-peptide levels that are within the normal range; in others, these values are low despite the marked stimulation by fasting hyperglycemia. In most patients, the endogenous insulin and C-peptide responses to secretagogues are low.

Some type 1 diabetic patients go into remission, a so-called "honeymoon" period, usually within a few months of the institution of insulin treatment and the resultant improvement in glycemic control. During this honeymoon phase, the requirement for exogenous insulin decreases and C-peptide levels usually rise, indicating a resurgence of endogenous insulin secretion from the residual β cells. The mechanism responsible for this improvement in insulin secretion is unknown. One theory is that chronic severe hyperglycemia overdrives the residual β cells and desensitizes or exhausts them. Then, treatment with exogenous insulin lowers the plasma glucose level, reducing the drive and allowing the residual β cells to recover and to regain partial function. Unfortunately, the honeymoon period is usually transient, perhaps because of continuing autoimmune damage of the residual β -cell population.

Type 2 Diabetes The pathophysiology of the hyperglycemia and the compensated insulin secretion of T2DM is described in detail in Chap. 21. Therefore, only a brief outline will be given here. Near-

total β -cell loss, a prominent feature of type 1 diabetes, is not a major feature of type 2 diabetes. Morphometric studies suggest that type 2 diabetic patients have lost at most 50% of their β cells. Because a 50% β -cell loss in experimental animals does not produce the fasting hyperglycemia seen in type 2 diabetes, additional factors, such as a dysfunction of the remaining β cells or concomitant insulin resistance, must contribute. Part of the β -cell dysfunction, particularly in the late stages of type 2 diabetes, may be due to the formation of the islet amyloid^{13,149} via its inhibitory and eventually cytotoxic effect on β cells.¹⁵⁰

In animals with selective impairment of insulin secretion, the resulting hyperglycemia is the dominant factor that maintains the fasting insulin and acute insulin responses to nonglucose secretagogues in the normal range.²¹⁵ The same is true in patients with T2DM. For example, when the glucose levels of type 2 diabetics is lowered to those of normal individuals, the basal insulin level and the acute insulin responses to nonglucose stimuli become clearly abnormal.¹⁵⁸ Indices of β -cell function that are independent of plasma glucose level or that account for the effect of hyperglycemia also reveal a marked impairment of insulin secretion: PI:IRI is increased, AIR to glucose is absent, and the slope of glycemic potentiation and AIR_{max} are both markedly reduced; PG₅₀ is normal.^{176,177} Thus there is a major reduction in the capacity of type 2 diabetic patients to secrete insulin despite normal sensitivity of the β cells to the potentiating effects of glucose.

Controversy exists regarding the primacy of the contribution of defects in insulin sensitivity versus insulin secretion to the development of T2DM. Although both defects are present, type 2 diabetes rarely occurs without impaired insulin secretion, and studies of first-degree relatives of type 2 diabetic patients report β -cell dysfunction as an early lesion in this disease.²²⁵ Further, careful studies in groups at high risk for the development of T2DM reveal that they have an impairment of insulin secretion relative to the amount of their insulin resistance.^{153,226–231} Many investigators believe that subjects with mild defects in insulin secretion do not present with clinical type 2 diabetes until they become sufficiently insulin resistant. In Western societies a common form of insulin resistance occurs in late middle age associated with increased abdominal obesity. This insulin resistance is thought to increase the demand for insulin secretion to the point where the defective β cell is unable to compensate.^{182,232–235} This attractive model of type 2 diabetes pathogenesis was confirmed earlier in primates with combinations of β -cell toxins and agents causing insulin resistance,¹⁷⁰ and more recently in mice with a gene knockout which impairs both insulin secretion and action.^{187,188,193}

CONCLUSIONS

In vivo, pancreatic β cells adjust their output of insulin to compensate for changes in the sensitivity of tissues to insulin or for changes in β -cell number or function. Both the defect that elicits the compensatory response, and the compensatory response of the β cells themselves, can be reflected in indices of insulin secretion and β -cell function (Table 4-2). However, two generalizations are worthy of emphasis. First, the compensatory insulin response to insulin resistance is best reflected in the increase of the fasting insulin level. The usual accompanying glucose intolerance suggests that the compensation is not complete, but rather just sufficient to prevent fasting hyperglycemia. Second, the compensatory insulin response to partial β -cell loss or dysfunction usually normalizes

the fasting insulin level, excluding its use as an index of β -cell loss or dysfunction. The slope of glycemic potentiation and AIR_{max} are, however, decreased in approximate proportion to the degree of β -cell loss or dysfunction, thus providing clear evidence of a defect.

The important implication of this last conclusion relates to the detection of latent diabetes in susceptible individuals. It seems likely that those measures of islet dysfunction that either take into account the ambient glucose level (slope of glycemic potentiation, PG₅₀, and AIR_{max}) or are independent of it (AIR to glucose) could detect β -cell dysfunction in individuals before it is severe enough to result in the fasting hyperglycemia characteristic of diabetes. In addition, relating these measures to the degree of insulin resistance has allowed the identification of individuals with subtler β -cell defects.²³⁶ Currently, major effort is being expended to identify individuals at high risk for development of both type 1 and type 2^{237,238} diabetes, because they are candidates for the therapeutic trials that might delay or prevent the onset of clinical diabetes.

Mechanisms of Insulin Action

Jes K. Klarlund

Bruce R. Conway

Barbara VanRenterghem

Michael P. Czech

Although the hormone insulin and its specific cell membrane receptor share characteristics with many peptide growth factors and their receptors, insulin plays a unique role in human biology. Its absence uniquely causes major abnormalities in multiple metabolic pathways and is lethal. In adults, the major actions of insulin lead to increased synthesis of protein, glycogen, and fat, thereby promoting muscle strength and energy reserves when food is available. The signaling systems that mediate these anabolic responses to insulin regulate key controlling enzymes in these respective metabolic pathways. In general, these regulated enzymes are stimulated or inhibited by insulin through phosphorylation of protein serine/threonine residues or by dephosphorylation of such sites. Because the insulin receptor is a tyrosine kinase, the general underlying feature of insulin signaling is switching the initial receptor-mediated tyrosine phosphorylation to modulation of protein serine/threonine protein kinases and protein serine/threonine phosphate phosphatases. Over the past several years it has been recognized that one switch is the proto-oncogene product p21 ras, which binds guanosine triphosphate (GTP) in response to insulin and initiates activation of Raf protein kinases and in turn a cascade of other serine/threonine protein kinases (for reviews, see references 1 and 2). This pathway appears to play a major role in mediating effects of insulin on cell proliferation. Another switching mechanism involves the activation of a lipid kinase, phosphatidylinositol-3-kinase (PI-3-kinase), which catalyzes the formation of 3' polyphosphoinositides that in turn initiate recruitment and activation of the serine/threonine protein kinases Akt (also denoted protein kinase B) and certain protein kinase C isoforms (for reviews, see references 237–240). Many of the metabolic effects of insulin appear to be regulated by this pathway. This new information allows us for the first time to trace the molecular circuitry of insulin signaling pathways from the receptor tyrosine kinase through downstream events that regulate metabolic pathways.

Activation of the Raf protein kinase cascade and Akt by insulin leads to extensive protein phosphorylations on serine/threonine residues in target cells within minutes of exposure to the hormone. This stimulation of protein phosphorylation by insulin in ³²P-labeled cells is quantitatively greater than the enzyme dephosphorylations that also occur, and can be easily visualized by elec-

trophoretic analysis of whole-cell extracts. Several major proteins are targets of such phosphorylation in addition to the above protein serine/threonine kinases themselves, including the forkhead transcription factor (X5 and X6), S6 ribosomal protein,³ ATP citrate lyase,^{4,5} acetyl CoA carboxylase,^{6,7} PHAS,^{8–10} and several unidentified species. The insulin receptor is also serine/threonine phosphorylated in response to insulin binding in intact cells.¹¹ Although increased serine/threonine phosphorylation of cellular proteins is a major effect of insulin, in many instances the physiologic effect of these proteins has not been determined. However, recent exciting data indicate that insulin-mediated phosphorylation of PHAS dramatically modulates its activity and plays a major role in increasing protein synthesis. Also, phosphorylation of forkhead in response to insulin appears to play a major role in regulating transcription of hepatic enzymes involved in gluconeogenesis.²⁴²

New information has also yielded insights into how enzyme dephosphorylations may occur in response to cell signaling by insulin. Such dephosphorylations include that of glycogen synthase which increases the activity of the enzyme, leading to increased glycogen deposition,¹² and hormone-sensitive lipase, which inhibits its activity and the hydrolysis of triglyceride stores.¹³ Similarly, pyruvate dehydrogenase is dephosphorylated and activated in response to insulin,¹⁴ leading to increased synthesis of acetyl CoA and fatty acids. Regulation of protein serine/threonine phosphate phosphatases appears to involve their recruitment to target enzymes. This recruitment may result from the action of one or more protein serine kinases on regulatory subunits of the protein phosphatase 1.¹⁵ However, recent results show rather normal insulin responsiveness of glycogen synthase activity in mice where such a major regulatory subunit is ablated through gene knockout techniques.²⁴⁴ Thus there may be other phosphatases involved in these insulin actions. The identity of such hypothetical insulin-sensitive phosphatases is an important area of future investigation. In addition, decreased protein kinase activity in response to insulin has been established as a possible mechanism of protein dephosphorylation, as discussed below in reference to glycogen synthase regulation.

Taken together, the above considerations indicate that understanding the molecular basis of insulin's actions will depend on

defining the many molecular elements involved in linking the insulin receptor tyrosine kinase to target protein serine/threonine phosphorylations and dephosphorylations. This review summarizes our current understanding of such signaling elements, using insulin's actions on glucose transport, protein synthesis, and glycogen synthesis to exemplify their mechanisms of action.

THE INSULIN RECEPTOR

The insulin receptor is a large heterotetrameric transmembrane glycoprotein that is expressed in nearly all vertebrate tissues at levels ranging from as few as 40 receptors per cell in circulating erythrocytes to over 200,000 receptors per cell in adipocytes.^{18,19} The receptor is composed of two 723-amino-acid polypeptide α subunits that are each linked to a β subunit (620 amino acids) and to each other by disulfide bonds, forming a functional dimeric protein complex (Fig. 5-1).¹⁸⁻²¹ The extracellular α subunits contain the insulin binding domain,²²⁻²⁴ and the transmembrane β subunits contain the insulin-regulated tyrosine kinase domain.^{25,26} Both subunits are derived from a single proreceptor by proteolytic processing at a site consisting of four basic amino acids.²⁷⁻²⁹ Noncovalent dimerization of ligand-bound receptor tyrosine kinases is generally observed,^{30,31} but the insulin receptor (along with the closely related IGF-1 receptor and insulin-related receptor^{32,33}) is unique in that the unbound receptor is maintained in the basal state as a covalent dimer.³⁴

The insulin receptor gene is located on the short arm of human chromosome 19, near the low-density lipoprotein (LDL) receptor gene, and encodes a 4.2-kb mRNA, despite its 150-kb length.³⁵ The large size of the insulin receptor gene may lead to an increased susceptibility to random mutation, and hence to receptors with altered

biochemical activity. Alternative splicing of the receptor mRNA at exon 11 produces two nearly identical isoforms differing by 12 amino acids at the carboxyl-terminus of the α subunit.^{36,37} These receptor variants are termed HIR-A (human insulin receptor, variant A, Ex112, lacking the 12 amino acids of exon 11) and HIR-B (Ex111). Although these isoforms are reported to exhibit subtle biochemical and physiologic differences,^{38,39} changes in receptor protein isoform expression levels have not been consistently found in patients with diabetes mellitus.^{29,40}

The binding of insulin to its receptor occurs with a stoichiometry of between 1 and 2 insulin molecules per receptor, and displays negative cooperativity as determined by Scatchard analysis.⁴¹ Identification of the insulin-binding site or sites has been an important goal due to the implications such a finding has on the design of insulin analogs for therapeutic use. Although the exact sequences of the insulin receptor that directly associate with hormone are still being defined, the ligand-binding domain has been broadly mapped to the first 500 amino acids of the α subunit.⁴²⁻⁴⁴ Use of various techniques such as affinity labeling, epitope mapping, *in vitro* mutagenesis, and construction of IGF-1/insulin receptor chimeras has allowed the identification of hormone-binding determinants within distinct regions of the α -subunit amino terminus.¹⁹ Mutations in other regions of the α subunit can also adversely affect insulin binding, indicating that the hormone-binding site is created by the three-dimensional structure of the α subunit and does not rely solely on a linear segment of primary amino acid sequence.¹⁸

Once insulin is bound to the receptor, the β subunits undergo rapid autophosphorylation on tyrosine residues in the intracellular juxtamembrane domain (Y960, numbering of HIR-A, Ex112),²⁷ the regulatory region within the kinase domain (Y1146, Y1150, Y1151), and the carboxyl terminus (Y1316, Y1322).^{18,19,29} Tyrosine autophosphorylation appears to occur through a trans-mechanism in which insulin binding to the α subunit of one $\alpha\beta$ dimer stimulates the phosphorylation of the adjacent covalently bound β subunit.⁴⁵ Hormone binding appears to relieve an inhibitory constraint imposed by the extracellular domain of the receptor on its tyrosine kinase activity. This observation is based on several studies showing that proteolytic cleavage or mutagenesis of the extracellular domain results in constitutive receptor tyrosine kinase activity.⁴⁶⁻⁴⁹ Consistent with these findings, crystallographic studies have shown that in the absence of insulin, the receptor's cytoplasmic domains bind and block its own active sites via a cis-inhibitory mechanism. This inhibition is relieved by insulin binding, which induces a conformational change in the receptor such that trans-tyrosine autophosphorylation and activation can occur.⁵⁰ Thus the insulin receptor behaves as a classic allosteric enzyme with both regulatory (α) and catalytic (β) subunits. Further analysis of the insulin receptor tyrosine kinase domain in the tyrosine phosphorylated state by x-ray crystallography has revealed a major change in the conformation of an inhibitory loop that blocks catalytic activity of the kinase (325). Thus the action of autophosphorylation of the receptor kinase to increase tyrosine kinase activity of the receptor can be explained at high resolution.

The autophosphorylation of the regulatory region increases the activity of the receptor tyrosine kinase 10- to 20-fold, leading to greatly increased tyrosine phosphorylation of cellular proteins, such as IRS-1 and Shc.^{51,52} The activation of the receptor tyrosine kinase also permits transmission of the insulin signal to metabolic pathways, such as glucose transport, glycogen synthesis, protein synthesis, and lipid metabolism, within the cell.¹⁹ The receptor is also phosphorylated on both serine and threonine residues by cellu-

FIGURE 5-1. Structural features of the insulin receptor. The insulin receptor is a heterotetramer with two α and two β subunits linked by interchain disulfide bonds (—SS—). The α and β subunits are synthesized as a single polypeptide prior to proteolytic cleavage. The α subunits reside entirely on the extracellular surface. Numbering of individual amino acid residues are as in HIR-A, Ex11-.¹⁰ **Open rectangles**, ligand-binding domains. **Filled rectangles**, juxtamembrane region. **Filled circles**, ATP-binding region. **Open oval**, regulatory region (Y xx YY). All tyrosines (Y) shown can be phosphorylated upon receptor activation.

lar kinases both in the basal state and after stimulation by phorbol esters, cyclic AMP analogs, and prolonged insulin treatment.^{53,54} These phosphorylation events are often inhibitory to the receptor tyrosine kinase,^{54,55} and provide an additional level of control that may play an important role in altering receptor activity in both physiologic and pathologic states. The combination of hormone binding, tyrosine autophosphorylation, and serine/threonine phosphorylation appear to comprise a complex network of regulatory mechanisms for maintaining appropriate insulin receptor function.

Numerous mutational studies have been performed to address the contribution of various domains and individual amino acid residues on ligand–receptor binding, receptor activation mechanisms, and intracellular signaling pathways, as well as receptor regulation and internalization. Although much of this information remains controversial, there have been some notable findings. Among these discoveries is that the tyrosine kinase activity of the receptor is essential for the metabolic and growth-promoting actions of insulin and for receptor internalization. Introduced mutations at the conserved lysine residue (K1018) in the kinase ATP-binding pocket abolish receptor tyrosine kinase activity and signaling,²⁶ and naturally occurring receptor mutations in this region have been found in cells of insulin-resistant individuals.^{56–58} Numerous studies have also found that autophosphorylation of the regulatory region within the kinase domain is essential for regulating the kinase activity of the receptor towards endogenous substrates, such as IRS-1, and for the generation of metabolic signals, particularly glucose transport and glycogen synthesis, from the receptor (reviewed in reference 59).

In addition to signal transduction, the insulin receptor mediates internalization of itself bound to hormone. Endocytosis of this complex leads to insulin degradation and recycling of receptors back to the plasma membrane.¹⁹ It appears that signaling by the insulin receptor in endosomes may be limited,²⁴⁶ and is not required for its action on glucose utilization.²⁴⁷ Interestingly, both the PI-3-kinase and MAP kinase pathways may be involved in regulating insulin receptor endocytosis and downstream trafficking.²⁴⁸ Other proteins implicated are the GTPase Ral²⁴⁹ and sorting nexins.²⁵⁰ Although the mechanism by which the hormone–receptor complex is internalized is still under investigation, available evidence indicates the existence of more than one pathway for this process.^{60,61} Aggregation of receptors into coated pits is a common initial endocytic step for many receptors, and is likely also a major pathway used by the insulin receptor.^{61–63} In cases of prolonged insulin

stimulation, as is seen in patients with type 2 diabetes mellitus (T2DM),⁶⁴ receptors are degraded along with hormone, resulting in receptor downregulation and attenuation of the insulin signal.^{65,66} These cases of hyperinsulinemic downregulation have been reported to cause selective loss of the HIR-A variant, as these receptors are preferentially occupied, internalized, and degraded.^{37,39,67} Although insulin receptor internalization may not be required for full insulin action,¹⁸ the internalized receptor is still catalytically active.⁶⁸ Impaired receptor internalization has been observed in cells of patients with T2DM,⁶⁴ suggesting that some element of the insulin signaling pathway is defective and may contribute to the disease state.

INSULIN RECEPTOR SUBSTRATES

In addition to the multisite tyrosine phosphorylation of the β subunit of the receptor, several endogenous candidate substrates for the insulin receptor tyrosine kinase have been identified in insulin-responsive tissues such as muscle, adipose tissue, and liver. These putative substrates appear to initiate events that lead to protein serine/threonine kinase and protein serine/threonine phosphate phosphatase regulation. The proteins in intact cells that are tyrosine phosphorylated (Table 5-1) in response to insulin include the first identified insulin receptor substrate, referred to as IRS-1,^{73,76} and the Src homology collagen (Shc) protein, which has several forms.⁶⁹ Several isoforms of IRS-1 have now been identified, including IRS-2,²⁵¹ IRS-3,²⁵² and IRS-4.²⁵³ The insulin-dependent tyrosine phosphorylation of several other substrates has also been reported, including Gab-1,²⁵⁴ APS,^{255,256} CAP,²⁵⁷ Grb10,^{258,259} and pp62Dok.²⁶⁰ The full functional significance of these latter substrates is in the process of being determined. Therefore, we shall emphasize the best characterized tyrosine phosphorylated substrates (IRS-1 and related isoforms, and Shc) in this section and the next.

IRS-1 was initially identified as a 185-kd phosphoprotein present in antiphosphotyrosine immunoprecipitates from insulin-stimulated Fao hepatoma cells.⁷³ It is rapidly tyrosine phosphorylated in response to insulin in a dose-dependent manner. IRS-1 has been identified in virtually all insulin-sensitive cell types examined including rat myoblasts, Chinese hamster ovary cells, and adipocytes from rat, mouse, and humans (reviewed in reference 74). IRS-1 was successfully purified from liver extracts,⁷⁵ and

Table 5-1. Cellular Targets of Tyrosine Phosphorylation in Response to Insulin

Phosphoprotein	Role of Tyrosine Phosphorylation	Possible Physiologic Role of Phosphoprotein
Insulin receptor	Receptor kinase activation	Tyrosine phosphorylate substrates and initiate insulin actions
Insulin receptor substrate (IRS) proteins 1–4	Binding of SH2-containing proteins	
	Binding and activation of PI-3-K	Activation of Akt
	Binding and activation of SHP2	Activation of p21ras
	Binding and activation of Grb-2	Activation of p21ras
	Binding and activation of Nck	Actin polymerization
Gab-1	Binding of Grb2	Activation of p21ras

Grb10		Negative regulator of insulin receptor kinase

sufficient amino acid sequences of peptides were obtained to allow cloning of the full-length cDNA from a rat liver library.⁷⁶ Comparison of IRS-1 cDNA clones from the rat liver, mouse 3T3-L1 adipocytes,⁷⁷ and human skeletal muscle⁷⁸ reveals striking similarity at the nucleotide and amino acid level. Analysis of the IRS-1 amino acid sequence reveals a number of potential functionally important motifs, including a possible nucleotide-binding site near the amino-terminus and a pleckstrin homology (PH) domain between amino acid residues 7 and 120. PH domains are found in a variety of signaling molecules⁷⁹ and have been postulated to mediate protein-protein or protein-lipid interactions. In the case of IRS-1, the PH domain has been shown to be crucial for its proper engagement with the insulin receptor.^{261,262} The PH domain appears to act in tandem with an adjacent domain, the PTB domain, in specifically orienting its association with the insulin receptor for optimal tyrosine phosphorylation.²⁶³ PTB domains are known to bind directly to phosphotyrosine-containing peptides,^{264,265} and in the case of the insulin receptor, tyrosine 960 in its juxtamembrane domain has been identified as the binding site for the IRS-1 PTB module.²⁶⁶ Amino acid residues N-terminal to this tyrosine phosphate participate in defining the specificity of PTB domain binding. The PTB domains of the IRS isoforms are highly similar in amino acid sequence. Thus the combined actions of the PH and PTB domains of all the IRS proteins are thought to direct the physical association of these substrates to the insulin receptor. In addition, interactions of these domains with the insulin receptor are likely highly regulated by signaling mechanisms designed to control the strength of the signals emanating from the receptor.²⁶⁷

The most prominent feature of the IRS-1 molecule is the presence of at least 20 potential tyrosine phosphorylation sites, including 6 that occur in a repetitive motif YXXM, and 3 that present within a YXXM motif. Multiple potential tyrosine phosphorylation sites are also a prominent feature of the structures of the other IRS proteins.²⁶⁸ Recent studies have unveiled a specialized functional role for tyrosine phosphorylated YXXM/YXXM motifs in the recognition of a specific protein domain homologous to a region of the Src tyrosine kinase referred to as the Src homology (SH)2 domain. SH2 domains are present in many intracellular signaling molecules, and bind with high affinity to specific phosphotyrosine motifs, thus creating the basis for specific protein-protein interactions within the cell. Moreover, several SH2-containing proteins possess intrinsic catalytic activities that appear to be regulated upon binding to specific phosphotyrosine motifs. IRS-1 also contains at least 35 potential serine or threonine phosphorylation sites, including recognition motifs for cyclic AMP-dependent protein kinase, protein kinase C, casein kinase II, and cdc2 kinase. IRS-1 is highly phosphorylated on serine and threonine residues; however, the exact residues and the functional significance of these phosphorylations in the intact cell are currently being defined.²⁶⁹ Insulin action reportedly enhances phosphorylation of IRS-1 at a casein kinase II site.⁸⁰ Insulin also appears to initiate a feedback inhibition loop whereby the downstream protein serine/threonine kinase Akt phosphorylates IRS to cause inhibition of its function.²⁷⁰

The presence of multiple phosphorylated tyrosyl residues on IRS proteins, each with a selective binding specificity for PTB- or SH2-containing proteins, provides a mechanism for divergence of the insulin signal. According to this paradigm, tyrosine phosphorylation of IRS-1 and its isoforms provides a stage for the assembly of multimolecular signaling complexes and represents a potential pivotal point at which insulin-mediated metabolic and mitogenic

responses might diverge.⁷⁰⁻⁷² Because EGF and PDGF receptors fail to phosphorylate IRS-1,⁷³ such a mechanism also provides a level of specificity regarding the molecular events unique to insulin action. Several signaling molecules have been demonstrated to bind, in an insulin-dependent manner, to specific phosphotyrosine motifs on IRS-1 and its isoforms. These proteins include the p85/p110 type PtdIns 3' kinase, which is required for the activation of one major switch mechanism to activate protein serine/threonine kinases. A second set of interacting proteins include the growth factor receptor-bound protein-2 (Grb2), the protein tyrosine phosphatase Syp/SHP2, and the adaptor Shc, all of which are involved in activating a second major pathway through the proto-oncogene GTPase p21Ras. How these proteins may contribute to the downstream actions of insulin will be briefly described.

The p85/p110-type PtdIns 3' kinase is one of several lipid kinases responsible for the phosphorylation of phosphoinositides on the 3-position of the D-myo-inositol ring. This enzyme produces PtdIns(3)P, but also the multiphosphorylated PtdIns(3,4)P₂ and PtdIns(3,4,5)P₃ products. The physiologic role of these novel phospholipids has been studied extensively, and several downstream effector domains characterized, including FYVE and PX domains [PtdIns(3)P]²⁷¹ and certain PH domains [PtdIns(3,4)P₂ and PtdIns(3,4,5)P₃].²⁷² The p85/p110-type PtdIns 3' kinase activation has been linked to several biologic actions, including glucose transport regulation, glycogen synthesis, growth factor-stimulated mitogenesis, and cellular growth. The enzyme is comprised of a 110-kd catalytic subunit (p110) and an 85-kd regulatory subunit (p85), which contains two SH2 domains and a single SH3 domain. PtdIns 3' kinase was the first enzymatic activity shown to associate with tyrosine phosphorylated IRS-1.⁷⁶ More recently, *in vitro* studies indicate that phosphotyrosines at positions 608 and 939 of IRS-1⁸¹ preferentially bind to the SH2 domains of p85, thus enhancing PtdIns 3' kinase activity. This IRS-mediated pathway is illustrated in Fig. 5-2A. It is clear that binding of this lipid kinase is a major

FIGURE 5-2. Elements of the PI-3-kinase pathway. **A.** The insulin receptor catalyzes tyrosine phosphorylation of IRS proteins which recruit the p85 regulatory subunit of PI-3-kinase to the membrane, where the catalytic p110 subunit phosphorylates PtdIns(4,5)P₂ to produce PtdIns(3,4,5)P₃. **B.** Membrane-bound PtdIns(3,4,5)P₃ attracts the protein serine/threonine kinases PDK1 and Akt to the membrane through binding their PH domains, where PDK1 phosphorylates and activates Akt. Other protein kinases are also phosphorylated and activated by PDK1, while substrates of Akt include the protein kinase GSK3, transcription factors forkhead and CREB, and the apoptosis-related protein BAD.

function of all the IRS proteins, and that activation of its downstream protein serine/threonine kinases represents a major pathway for the regulation of metabolic processes by insulin in its target tissues.²⁶⁸

Another cellular component capable of binding specifically to IRS-1 is Grb2,⁸¹ a protein first characterized by its ability to bind directly to tyrosine-phosphorylated EGF receptors.⁸² Grb2 is devoid of catalytic activity and is comprised of a single SH2 domain flanked by two distinct protein-binding domains that share significant homology to a region of the Src tyrosine kinase referred to as the SH3 domain. SH3 domains recognize proline-rich sequences, thus mediating specific protein-protein interactions.^{83,84} The SH2/SH3-containing Grb2 molecule is particularly interesting, because it binds the ras activating protein, Son-of-sevenless (Sos).^{85,86} Therefore, one possible consequence of insulin-dependent formation of IRS-1:Grb2:Sos complexes is the activation of ras.⁶⁹ It has been suggested that IRS-1 is indispensable for insulin-stimulated mitogenesis and cell-cycle progression⁸⁷; however, gene knockout experiments demonstrate that IRS-1 is not required for insulin-mediated responses to be observed in intact animals.^{88,89} The ability of insulin to stimulate mitogen-activated protein kinase in livers of normal mice and those homozygous for the IRS-1 knockout was indistinguishable. Moreover, replacement of the specific Grb2 recognition site on IRS-1 (tyrosine 895) with phenylalanine fails to abrogate insulin-induced mitogenesis.⁹⁰ These results provide evidence for an IRS-1-independent pathway that contributes to the mitogenic response that may involve Grb2 association with other putative insulin receptor substrates such as other IRS protein isoforms or Shc.

The microtubule-activated GTPase dynamin also binds to the SH3 domain(s) of Grb2 through a proline-rich region present in its COOH-terminal domain.^{91–93} Evidence suggests that the dynamin GTPase activity is increased upon binding to the Grb2 SH3 domain.⁹¹ Insulin stimulation results in the formation of a heterotrimeric complex between IRS-1 and Grb2:dynamin. GTPase activity is stimulated when a phosphotyrosine peptide containing the Grb2 binding site of IRS-1 is added to the dynamin:Grb2 complex in a cell-free system.⁹⁴ The precise role that the dynamin plays in receptor-mediated signaling events remains unclear; however, several recent reports suggest a functional role in receptor-mediated endocytosis⁹⁵ and clathrin-coated vesicle function.⁹⁶ Mutations within the GTP binding site of dynamin block receptor-mediated endocytosis at a stage following coat assembly and preceding the sequestration of ligand into deeply invaginated coated pits.⁹⁵ The next critical step is to precisely define the functional role, if any, of IRS-1:Grb2:dynamin complex formation in the insulin-induced endocytic event.

A third SH2-containing molecule capable of binding to phosphorylated IRS-1 in response to insulin is the protein tyrosine phosphatase, Syp/SHPTP2/SHP2.^{81,97} SHP2 contains two SH2 domains, both of which are believed to mediate binding to tyrosine-phosphorylated IRS-1.⁹⁸ A systematic analysis of the relative binding affinities of various IRS-1 phosphopeptides for the amino- and carboxy-terminal SH2 domains of SHP2 revealed preferential binding of phosphotyrosine residues 1172 and 1222, respectively.^{98,99} These IRS-1 phosphopeptides specifically stimulate SHP2 phosphatase activity up to 50-fold *in vitro*, suggesting that SHP2 represents a second enzymatic activity regulated upon association with IRS-1. Recent investigations using a catalytically inactive SHP2 mutant, which still binds IRS-1, demonstrate that insulin-dependent formation of the IRS-1:SHP2 complex may con-

tribute to insulin-induced ras activation;^{100,101} however, the molecular mechanism for this role of SHP2 has yet to be elucidated.²⁷³

SHP2 also binds directly to the SH2 domain of Grb2 in response to PDGF.¹⁰² This interaction is presumably a reflection of PDGF-induced tyrosine phosphorylation of SHP2.^{102,103} Insulin receptor activation does not result in the tyrosine phosphorylation of SHP2,⁹⁷ a finding consistent with the inability to detect a complex of SHP2 and Grb2 after insulin treatment.¹⁰¹ In any event, the ability of SHP2 to associate with IRS-1 in an insulin-dependent manner suggests this protein may be one of many participants in the cascade of events mediating the biologic actions of insulin.

Several variant sequences in the IRS genes have been reported to be increased in prevalence among patients with T2DM, for example the Gly to Arg72 substitution in IRS-1 that seems to have a pathogenic role.^{104,274–278} The regulation of insulin signaling through IRS-1 has been studied in several models of diabetes, including the insulin-deficient streptozocin (STZ)-treated rat and the insulin-resistant ob/ob mouse.^{74,105} These studies demonstrate that IRS-1 phosphorylation parallels that of insulin receptor phosphorylation, suggesting that the tyrosine kinase activity of the receptor is rate-limiting in the cascade of events following insulin administration to diabetic animals. Furthermore, in diabetic animals the level of IRS-1 protein is differentially regulated in liver and muscle. In the liver, IRS-1 protein is increased in hypoinsulinemic states and decreased in hyperinsulinemic states, whereas the converse is observed in muscle. Collectively, these data suggest that IRS-1 is centrally located within the insulin-signaling pathway and, by virtue of its ability to assemble multimeric protein complexes, is uniquely positioned to orchestrate biologic responses to insulin. Recent studies using cells with low endogenous levels of IRS-1, such as oocytes¹⁰⁶ and 32-D myeloid progenitor cells,¹⁰⁷ provide evidence that IRS-1 is critical for the restoration of insulin-dependent cell-cycle progression. Furthermore, IRS-1-deficient mice exhibit impaired growth and development as well as some resistance to the glucose-lowering effect of insulin.^{279–282} Insulin signaling is also dramatically impaired in mice with only one allele each of the insulin receptor and IRS-1 genes.²⁸³ Therefore, IRS-1 appears to be necessary for normal growth and metabolism. Similarly, it is likely that IRS-2 also contributes significantly to glucose homeostasis, based on studies with IRS-2-deficient mice, and this includes significant effects both in the peripheral tissues,^{284–286} and in the β cells²⁸⁷ of the pancreas which produce and secrete insulin. Taken together, these studies of mice with ablated IRS genes fully support a central role of IRS-1 and IRS-2 in the mechanisms by which insulin signals to its target cells.

INSULIN ACTION THROUGH THE PI-3-KINASE SIGNALING PATHWAY

The generation of cellular 3' phosphoinositides by activation of the p85/p110 type PI-3-kinase through its recruitment to insulin receptor substrate proteins represents a major triggering event for a multitude of insulin's actions. These include many physiologically important metabolic effects, such as its regulation of glucose transport in muscle and fat, as well as its enhancement of glycogen synthesis and protein synthesis. The insulin-activated PI-3-kinase acts preferentially on PtdIns(4,5)P₂ to yield the signaling lipid PtdIns(3,4,5)P₃, as depicted in Fig. 5-2A. This mediator, as well as PtdIns(3,4)P₂ that is generated either by phosphorylation of PtdIns(4)P or dephosphorylation of PtdIns(3,4,5)P₃, appears in the

inner leaflet of the plasma membrane very rapidly upon insulin stimulation. This cell surface localization has been established through the use of PH domains that have high affinity and selectivity for binding PtdIns(3,4,5)P₃ or PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂.^{288–290} Phosphorylation of PtdIns to generate PtdIns(3)P also probably occurs in response to insulin, but this adds little to the total pool of PtdIns(3)P present in unstimulated cells. Thus the PI-3-kinase pathway of insulin signaling is thought to reflect downstream events initiated by the two 3' polyphosphoinositides described above.

The major downstream effector proteins of PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ in response to insulin are thought to be the protein kinases PDK1 and Akt.²⁹¹ As shown in Fig. 5-2B, both protein kinases are thought to localize to the plasma membrane through binding of their PH domains to these phosphoinositides. There is evidence that the higher affinity of the PDK1 PH domain for phosphoinositide compared to that of Akt renders the former protein kinase membrane-bound even in the absence of insulin.²⁹² According to this scheme, Akt is recruited to PtdIns(3,4,5)P₃ at the plasma membrane, thus allowing it to become a substrate for PDK1. Phosphorylation of Akt at threonine 308 by PDK1 and serine 473 by an unknown protein kinase causes activation of its protein kinase activity. The active form of Akt can presumably move to the cytoplasm as well as migrate to the nucleus, where it can phosphorylate substrates.

The PI-3-kinase cascade leads to the activation of multiple protein serine/threonine kinases based on the fact that both PDK1 and Akt can phosphorylate and activate several such enzymes (Fig. 5-2B). PDK1, for example, acts on the serum- and glucocorticoid-induced kinases,²⁹³ p70 S6K protein kinase,²⁹⁴ p21-activated protein kinase,²⁹⁵ and p90 RSK protein kinase,²⁹⁶ and two protein kinase C isoforms.²⁹⁷ Akt, on the other hand, phosphorylates and inactivates the protein kinase GSK3,^{298,299} which modulates glycogen synthase as discussed in detail in a later section. These protein kinases downstream of PDK1 and Akt each potentially have multiple substrates which can potentially regulate multiple cellular processes. Thus a tremendous diversity of cell functions can be regulated by the production of 3' polyphosphoinositides in response to insulin. These include nuclear functions. For example, the phosphorylation of the transcription factor forkhead by Akt occurs acutely in response to the hormone,^{300,301} but other kinases may also be critical to regulation of forkhead.³⁰² Recent evidence suggests that hepatic gluconeogenesis may in part be inhibited by insulin through this forkhead-mediated mechanism which regulates gene expression.³⁰³ Three other examples of signaling downstream of PDK1 are the regulation of glucose transport, glycogen synthesis, and protein synthesis, as discussed in detail below.

REGULATION OF GLUCOSE TRANSPORT

One of the most dramatic and important biologic functions of insulin *in vivo* is the rapid stimulation of glucose transport across muscle and fat cell membranes. This effect has been extensively studied both *in vivo* and in isolated cell systems, where effects of insulin in the 10- to 30-fold range are readily observed. Only fat and muscle cells exhibit this extraordinary responsiveness to insulin with respect to glucose uptake, and only these cell types express a particular glucose transporter protein isoform, GLUT-4¹⁰⁸ (also known as the insulin-regulated glucose transporter). In the absence of insulin, almost all of the GLUT-4 transporter is se-

questered in intracellular, tubulovesicular endosomal membrane structures, as visualized by immunoelectron microscopy.^{109,110} Fractionation of fat or muscle cells in the basal state leads to a low-density microsome preparation that is rich in GLUT-4 transporter protein. Addition of insulin to intact muscle or fat cells rapidly redistributes the GLUT-4 from the low-density microsomes to the plasma membrane fraction.^{111–113} Cell surface localization of GLUT-4 in response to insulin is confirmed by immunoelectron microscopy.^{109,110} A variety of independent techniques have further documented this major effect of insulin to cause GLUT-4 transporters to localize at the cell surface membrane, where they can catalyze glucose transport.^{113–116} It is not known whether additional effects of insulin are involved in regulating glucose uptake, such as an increase in the intrinsic catalytic activity of glucose transporter proteins.¹¹⁷

Data now available related to insulin action on glucose transport suggest two possible mechanisms whereby intracellular GLUT-4 in endosomal membranes may redistribute to the plasma membrane. The first possibility is that sequences within the GLUT-4 molecule cause intracellular retention of the protein by binding to putative intracellular membrane receptor species. According to this concept, such GLUT-4 receptors might prevent GLUT-4 from traveling back to the plasma membrane via endosomal recycling pathways. Consistent with this hypothesis, several laboratories have recently identified domains within the GLUT-4 transporter that appear to be necessary for intracellular sequestration. Three groups have identified the 30-amino-acid COOH-terminus of GLUT-4 as the major sequestration signal.^{118–120} Sequences within the middle region of GLUT-4 have also been suggested as influencing intracellular localization by two laboratory groups.^{118,121} It is not clear why earlier indications of a role for N-terminal sequences of GLUT-4 in maintaining its unique cellular localization¹²² have not been observed by other laboratories.^{118–120} However, experiments with chimera glucose transporters expressed in cultured adipocytes do appear to suggest some influence of the N-terminal region of GLUT-4 on its trafficking.³⁰⁴

Recently, a dileucine motif has been identified as the element within the COOH-terminal 30 amino acids of GLUT-4 that may be responsible for its sequestration signal.^{123,124} Other nearby acidic sequences may also be involved.³⁰⁵ Mutation of these leucines (residues 489 and 490) to alanines abolishes the ability of the GLUT-4 COOH-terminus to direct intracellular localization, although this may not be the case in cultured adipocytes.³⁰⁴ These experiments were conducted by utilizing chimera transporter constructs, linking regions of GLUT-4 to domains of the ubiquitously expressed GLUT-1 transporter isoform. GLUT-1 is predominantly a cell surface protein even in the basal state. Thus, substituting the 30-amino-acid COOH-terminus of GLUT-4, but not the dialanine mutant construct, confers an intracellular localization to this transporter chimera. It remains to be determined whether other domains of GLUT-4 act in concert with the dileucine motif, but the latter is clearly an important functional element. Importantly, these data lead to the hypothesis that an as-yet-unidentified receptor for this dileucine motif plays a role in GLUT-4 sequestration within the endosomal compartment. Furthermore, insulin action may cause disruption of this interaction between GLUT-4 and its dileucine receptor to cause release of GLUT-4 into the membrane recycling pathway. This hypothesis requires rigorous evaluation and testing in future studies.

A second mode by which insulin may regulate GLUT-4 redistribution to the plasma membrane is the stimulation of bulk intra-

cellular membrane flow to the cell surface. According to this hypothesis, GLUT-4 present in intracellular membrane compartments would be moved with these membranes as they translocate to the plasma membrane. This concept is consistent with several studies that indicate the major effect of insulin is to stimulate exocytosis of GLUT-4 from intracellular vesicles, although an insulin effect to inhibit endocytosis of GLUT-4 has also been observed.^{8,125,126} Estimations of the kinetics of endocytosis versus exocytosis of GLUT-4 in basal and insulin-stimulated cells indicate that GLUT-4 continuously recycles between plasma membrane and intracellular membranes in both conditions.

Further support for the concept that insulin causes bulk membrane movement to the cell surface has been recently reported. First, many other receptors and transporter proteins, such as GLUT-1, are also depleted in intracellular membranes upon insulin action, suggesting an effect even on proteins that lack the dileucine motif.^{127,128} Second, components that are involved in membrane docking and fusion events, such as Rab and guanine nucleotide dissociation inhibitor (GDI) proteins, are markedly modulated by insulin.^{129,130} Both Rab4 and the GDI2 isoform are released from endosomal membranes to the cytoplasm upon insulin action. This is consistent with the notion that insulin causes membrane movements and fusions, resulting in the rapid cycling of these proteins. Similar data have been presented for the synaptobrevin protein.¹³¹ The membrane proteins thought to be involved in the trafficking and fusion of GLUT-4-containing vesicles have recently been discussed in a review format.³⁰⁶ Finally, insulin causes a decreased amount of GLUT-4 vesicle mass when these membranes are purified from control versus stimulated adipocytes.³⁰⁷ Taken together, these results are consistent with the notion that insulin receptor signaling causes major changes in the dynamics of membrane recycling pathways and exocytosis of GLUT-4, causing increased concentrations of GLUT-4 and other proteins in these compartments at the cell surface.

The mechanisms by which insulin might cause intracellular membrane movements are not understood. However, recent data suggest the possibility that regulation of PI-3-kinase activity by insulin plays a key role in regulating glucose transporter redistribution to the plasma membrane. Important studies in yeast suggest that the product of the VPS34 gene, which displays PI-3-kinase activity, is an important element in membrane trafficking to the vacuole.¹³² Moreover, in mammalian cells it has been demonstrated that PDGF receptor trafficking to the lysosome depends upon its ability to bind PI-3-kinase.¹³³ Taken together, these data indicate that PI-3-kinase activity, presumably through 3' phosphoinositide reaction products, plays a major role in membrane trafficking phenomena in mammalian systems. Furthermore, several laboratories have demonstrated that insulin action on glucose transporter translocation is inhibited by highly specific PI-3-kinase inhibitors.^{134–136} Dominant negative regulators of PI-3-kinase also block insulin action on glucose transport.³⁰⁸ These data directly implicate, although do not prove, that the increased PI-3-kinase activity observed in the presence of insulin is necessary for GLUT-4 translocation.

Recent data have converged to strongly implicate Akt as a necessary signaling element downstream of PI-3-kinase in GLUT-4 regulation by insulin. First, expression of membrane-directed Akt in cultured adipocytes leads to sustained GLUT-4 translocation, mimicking the action of insulin.³⁰⁹ Secondly, a triple mutant dominant negative construct of Akt is inhibitory to insulin action on GLUT-4 when expressed in such adipocytes.³¹⁰ Finally, mice with

ablated genes for each of two isoforms of this protein kinase have been prepared. The double knockout is lethal, and the Akt1 knockout mouse shows no sign of deficient insulin action on glucose uptake in fat.³¹¹ However, mice lacking the gene encoding Akt2, the predominant isoform in fat, show insulin resistance and a defective responsiveness of glucose transport to insulin in both muscle and fat cells.³¹² Taken together, these results indicate that Akt likely plays a major role in mediating the action of insulin on GLUT-4 translocation. However, it should also be noted that very recent reports indicate there may be a PI-3-kinase-independent signaling pathway that operates in conjunction with Akt to cause GLUT-4 translocation. This pathway may involve binding of CAP to the insulin receptor, thereby attracting c-Cbl to the complex.³¹³ This in turn recruits the exchange factor C3G, which can activate the GTP-binding protein TC10.³¹⁴ This PI-3-kinase pathway may be required to mobilize F-actin filaments thought to be necessary for some step in the movement of GLUT-4-containing vesicles to the plasma membrane.^{315–319} Further studies will be required to clarify the role of this pathway in regulating GLUT-4.

REGULATION OF PROTEIN SYNTHESIS

It has long been recognized that insulin and other growth factors increase the rate of protein synthesis.^{195,196} Insulin stimulation appears to act primarily on the process of initiation of translation, in that insulin increases the number of initiated ribosomes.^{197–199} The binding of ribosomes to mRNA is facilitated by complexes of eukaryotic initiation factors (eIF).²⁰⁰ There are two steps in the initiation of translation where insulin might exert its effect. These are the attachment of the initiator methionyl-tRNA (met-tRNA_i) to the ribosome and the binding of mRNA.

The delivery of the initiator met-tRNA_i to ribosomes is mediated by the initiation factors eIF-2 and eIF-2B. The heterotrimeric G protein eIF-2 binds to met-tRNA_i in a GTP-dependent manner.¹⁹⁶ Following the formation of the ribosomal 80S initiation complex, eIF-2-bound GTP is hydrolyzed to GDP and the GDP-eIF-2 is released from the ribosome. Until its bound GDP is exchanged for GTP, eIF-2 cannot bind another met-tRNA_i. This GDP to GTP exchange is catalyzed by the guanine nucleotide exchange factor eIF-2B (formally called GEF).¹⁹⁶ Phosphorylation on serine 51 of the eIF-2 subunit has been shown to inhibit its ability to bind eIF-2B, which subsequently impedes translation.²⁰¹ It has been reported that insulin decreases eIF-2 α phosphorylation in calf chondrocytes.²⁰² Yet in Swiss 3T3 fibroblast, insulin or other growth factors have no effect on eIF-2 phosphorylation.²⁰³ However, insulin apparently does increase the activity of eIF-2B in Swiss 3T3 fibroblasts.²⁰³ *In vitro* eIF-2B is a substrate for casein kinase 1 and 2 and GSK-3, but it is disputed whether these phosphorylations have an effect on exchange activity.^{204–206} Likewise, it is not yet known if insulin changes the phosphorylation state of eIF-2B *in vivo*.

The initiation complex involved in binding mRNA is eIF-4F, which is composed of three polypeptides, eIF-4E, eIF-4A, and p220. Initiation factor eIF-4E recognizes the 5' 7-methylguanosine cap structure; eIF-4A is an RNA helicase, and p220 (also known as eIF-4 γ) is believed to be an RNA-binding protein. The binding of eIF-4F to RNA is followed by the binding of eIF-4B, which appears to stimulate the helicase activity of eIF-4A.^{200,207} Three of these initiation factors, eIF-4E, p220, and eIF-4B, have been shown to be phosphorylated in response to insulin.^{208,209} Although the functions of p220 and eIF-4B phosphorylations are not known,

mutating the major phosphorylation site of eIF-4E, serine 53, to an alanine results in the protein failing to bind to initiation complexes.²¹⁰ Thus a mechanism may exist where insulin exerts control over translation through the phosphorylation of these initiation factors.

A major breakthrough in determining how insulin controls the initiation of protein synthesis came with the discovery that the eIF-4E binding protein, 4E-BP1, is identical to the MAPK substrate PHAS.⁸ PHAS is a 12.4-kd heat- and acid-soluble protein that is phosphorylated in response to insulin. Moreover, serine 64, the major site in PHAS that is phosphorylated by insulin *in vivo*, is also phosphorylated by MAPK *in vitro*, indicating that MAPK phosphorylates PHAS directly upon insulin stimulation.^{10,211} In its unphosphorylated state, PHAS/4E-BP1 can bind to eIF-4E, but eIF-4E does not bind PHAS/4E-BP1 phosphorylated by MAPK *in vitro* or PHAS/4E-BP1 from insulin-treated adipose tissue. Furthermore, when eIF-4E is complexed to PHAS/4E-BP1, it no longer can bind to a 7-methyl GDP resin. Finally, PHAS/4E-BP1 can inhibit cap-dependent, but not cap-independent, translation *in vitro*.^{8,9} Taken together, these data suggest that in unstimulated cells, eIF-4E is bound to PHAS/4E-BP1, which inhibits translation initiation. Insulin stimulation results in the phosphorylation of PHAS/4E-BP1, which dissociates eIF-4E from PHAS/4E-BP1. This allows eIF-4E to bind to 5' caps and initiate translation.⁸

A major breakthrough in understanding how this pathway is regulated in intact cells resulted from experiments showing that the protein kinase mTOR, the target of rapamycin inhibition, accounts for phosphorylation of PHAS in intact cells.³²⁰ This mTOR protein kinase is downstream of PI-3-kinase, evidenced by its inhibition by wortmannin.³²¹ Furthermore, it was demonstrated that activation of Akt in intact cells leads to enhanced mTOR activity related to PHAS phosphorylation.³²¹ What is as yet unresolved is which protein kinases downstream of Akt directly phosphorylate mTOR in intact cells, and how they are apparently activated by Akt. Nonetheless, these new results clearly place control of protein synthesis by insulin within the PI-3-kinase/PDK1/Akt pathway.

REGULATION OF GLYCOGEN SYNTHESIS

A major consequence of insulin stimulation of muscle, fat, and liver is the rapid synthesis of glycogen.^{212–214} The rate-limiting step of glycogen metabolism is catalyzed by the enzyme glycogen synthase. Skeletal muscle glycogen synthase is an 80- to 84-kd protein that contains at least nine different serines that have been shown to be phosphorylated *in vivo*.^{213,215} Seven of these sites are clustered at the C-terminus of the protein, and the other two are located in the N-terminal region. Over 30 years ago, it was shown that the activity of glycogen synthase is inhibited by phosphorylation, and that insulin stimulates glycogen synthase through dephosphorylation.^{216,217} Insulin is believed to activate glycogen synthase by decreasing the phosphorylation of a C-terminal region that contains three serine residues, C30, C34, and C38.²¹⁸ A 24-hour insulin stimulation of rabbits has also been reported to dephosphorylate the N-terminal phosphorylation site serine N7.^{214,219} Thus it is apparent that in order for insulin to activate glycogen synthase, it must either activate phosphatases, inhibit kinases, or both.

The major phosphatase responsible for the dephosphorylation of glycogen synthase is protein phosphatase-1 (PP1).²²⁰ In skeletal muscle, a glycogen-bound isoform of PP1, PP1G, is involved in regulating glycogen synthase in response to insulin. PP1G consists of two subunits, a 37-kd catalytic (C) subunit and a 160-kd G

subunit required for the enzyme to interact with glycogen particles.^{221–223} Phosphorylation of the G subunit occurs at two separate sites, designated as site 1 and site 2. Site 2 is not phosphorylated in response to insulin, and its phosphorylation results in the dissociation of PP1G from glycogen particles, which subsequently decreases PP1G activity towards glycogen synthase.²²² Phosphorylation at site 1 is stimulated by insulin and results in an increase in the rate at which PP1G dephosphorylates glycogen synthase.¹⁵ In rat skeletal muscle, the kinase that phosphorylates the G subunit site 1 in response to insulin may be the p90 isoform of ribosomal protein S6 kinase,²²⁴ which is sometimes called MAP kinase-activated protein kinase-1 (MAPKAPK-1). This kinase itself is activated by phosphorylation catalyzed by MAPK, which thus was postulated to link the dephosphorylation of glycogen synthase in skeletal muscle to the activation of p21ras by the insulin receptor.¹⁹³ Remarkably, however, mice that have had the gene for the G targeting subunit ablated have recently been found to exhibit no apparent phenotype.³²² Moreover, their muscle glycogen synthase is readily activated by insulin. These new results confound the above postulates, and suggest there is another phosphatase involved in insulin action on glycogen synthase.

Another way in which glycogen synthase may be activated is through the inhibition of kinases that phosphorylate it. Although at least six different kinases can phosphorylate glycogen synthase, the three primary C-terminal serines believed to be dephosphorylated in response to insulin are all substrates for glycogen-synthase kinase-3 (GSK3).^{214,225} There are two isoforms of GSK3, α and β , which are 90% identical in their kinase domains.²²⁶ Besides glycogen synthase, GSK3 can phosphorylate a wide variety of other substrates, such as inhibitor 2 of PP1,²²⁷ type II regulatory subunit of cyclic AMP-dependent protein kinase,²²⁸ eukaryotic protein synthesis initiation factor (eIF-2B),²⁰⁶ and the transcription factors c-jun and c-myc.^{229,230}

Originally, GSK3 was thought to be constitutively activated. However, the α isoform of GSK3 was recently found to be identical to ATP citrate lyase kinase, which has been shown in rat fat cells to be deactivated by insulin.²³¹ Further studies have shown that the GSK3 α from skeletal muscle is phosphorylated by both p70 and p90 S6 kinases *in vitro*, and that this phosphorylation inhibits 80% of the GSK3 activity.²³² It has also been reported that in both CHO cells overexpressing the insulin receptor (CHOI) and in rat skeletal muscle L6 cells, wortmannin, which can inhibit p70 and p90 S6 kinase in some cells, blocks insulin's ability to deactivate GSK3. Moreover, insulin-stimulated GSK3 deactivation is not blocked by rapamycin, which inhibits p70 but not p90 S6 kinase.^{233,234} Thus the activity of GSK3, like PP1, is influenced by p90 S6 kinase and the ras-MAPK pathway. However, EGF also activates MAPK and p90 S6 kinase, yet it fails to activate glycogen synthase.^{214,235} Thus another pathway is required to fulfill this role.¹⁷ Again, the PI-3-kinase pathway appears to be the key to glycogen synthase regulation because wortmannin is found to inhibit insulin signaling to this enzyme. Furthermore, Akt has been shown to phosphorylate and inactivate GSK3,^{289,299} leading to the hypothesis that this inhibition contributes to glycogen synthase activation by insulin.

THE RAS-PROTEIN KINASE SIGNALING PATHWAY

The GTP-binding protein p21ras is the normal product of the first oncogene found in human neoplastic tissue. It exists in activated

forms in approximately one-third of human tumors, and it is therefore not surprising that p21ras is now one of the most extensively studied proteins.^{143–149} Four similar ras proteins have been identified, H-p21ras, K-p21rasA, K-p21rasB, and N-p21ras, each of which can function as an oncogene when carrying certain mutations, and a somewhat more distantly related nontransforming R-p21ras has also been identified. The protein p21ras is located at the plasma membrane, and this localization is essential for its biologic function.¹⁵⁰ Although inactive when bound to GDP, when bound to GTP, p21ras triggers a large number of cellular responses. The structural basis for the difference in activities of p21ras bound to the two nucleotides has been studied in great detail. Mutational analysis has shown that amino acids in the region 32–40 are of particular importance for interaction of p21ras with downstream effectors, and this has therefore been termed the effector region. Crystallographic analysis of p21ras bound to GDP or GTP has revealed that the effector region and another small region differ significantly in conformation in the two forms. Thus it is thought that interaction of the effector domain with critical cellular targets is crucial to transmission of downstream signals. Interestingly, p21ras has now been demonstrated to be involved in at least some of the intracellular signaling pathways of insulin.^{140–142, 151–154}

In the continuous presence of insulin, maximal GTP loading of p21ras is achieved after 2–5 minutes at 37°C.¹⁵⁵ This is followed by a deactivation phase, and the GTP content of p21ras returns to basal levels after 20–30 minutes. The nucleotide content of p21ras is determined by two reactions. It has an intrinsic weak GTPase activity, which converts bound GTP to GDP. This reaction can be enhanced up to 50-fold by the presence of certain proteins such as GAP and neurofibromin.¹⁵⁶ These proteins can therefore be seen as deactivators of p21ras, and inhibition of their activities may result in activation of p21ras. Such a mechanism appears to exist in T lymphocytes,¹⁵⁷ but may not be of significance in the p21ras response in insulin-sensitive tissues. The activities of GDP/GTP exchange factors offer a different route of p21ras activation. These factors cause the release of bound GDP from p21ras, followed by the spontaneous binding of GTP. Pulse-chase experiments using permeabilized cells have demonstrated that p21ras activation by insulin is brought about by increased exchange activities, rather than by decreases of GTPase activities.¹⁵⁸ Two closely related exchange factors, Son-of-sevenless (Sos) 1 and 2, are present in insulin-sensitive tissues,¹⁵⁹ as is a newly discovered exchange factor, C3G.¹⁶⁰ Sos is rapidly phosphorylated on serine and threonine after stimulation with insulin, but the role of this phosphorylation is at present unclear.

Insulin may cause p21ras activation primarily through tyrosine phosphorylation of the Shc family of proteins.^{161, 162} These proteins are ubiquitously expressed as three forms in cells. They all contain a carboxy-terminal SH2 domain, and have a glycine- and proline-rich region of homology to collagen in their amino terminal regions. As yet, no catalytic activity has been ascribed to Shc. Shc tyrosine phosphorylation results in the formation of complexes with Grb2 and Sos,^{155, 163} and such complexes could result in p21ras activation simply by recruiting Sos to its substrate, p21ras, at the cell membrane. Current results implicate a complex array of components involved in positioning Sos to interact with p21ras at the membrane,^{164, 165} as shown in Fig. 5-3. It is also possible that the intrinsic exchange activity of Sos is modulated in response to insulin, perhaps as a consequence of complex formation or as a result of phosphorylation.

The search for downstream targets for p21ras has been extensive, and recent progress has greatly enhanced our understanding

FIGURE 5-3. Hypothetical model of components involved in causing GTP loading of p21ras and activation of downstream targets by insulin. **A.** According to this model, insulin-receptor activation causes tyrosine phosphorylation of itself, recruiting Shc through its SH2 domain. The bound Shc is tyrosine phosphorylated by the receptor or by another tyrosine kinase, recruiting Grb2/Sos complexes through the SH2 domain of Grb2. The presence of a necessary component (**B**) that binds the N-terminal domain of Sos is suggested by recent results using truncation mutants of Sos.^{164, 165} **B.** Activation of p21ras leads to activation of the protein serine/threonine kinase Raf-1, which initiates a cascade that activates MAP kinase. MAP kinase regulates the protein kinase p90^{RSK}, and together they phosphorylate and regulate a transcription factor involved in controlling gene expression.

of the processes controlled by p21ras. Raf-1 is a 74-kd serine/threonine kinase that in mutated form acts as an oncogene.¹⁶⁶ The kinase domain resides in the carboxy-terminal part of the molecule, whereas the amino-terminal part is considered important in regulating the kinase activity, because mutations in this region activate the oncogenic potential of Raf-1. A prolonged search for a ligand that might bind to the regulatory domain of Raf-1 resulted in the discovery that it binds to p21ras specifically in the GTP-bound, biologically active form.¹ Mutations in the effector domain of p21ras that render it biologically inactive in cells also abolish Raf-1 binding. Binding of Raf-1 directly to p21ras explains the translocation from the cytosol to the cell membrane that Raf-1 undergoes in response to growth factors. Once bound to p21ras at the cell membrane, Raf-1 is activated. This appears not to be simply the result of binding to p21ras, because Raf-1 is not activated when bound to p21ras *in vitro*. When a membrane targeting signal is added to the carboxy-terminal part of Raf-1, the kinase was found to be constitutively active after transfection into COS-1 cells.^{167, 168} This was the case even when dominant negative mutants of p21ras were cotransfected, indicating that activation of Raf-1 is independent of p21ras function once the Raf kinase has been recruited to the plasma membrane. Thus the role of activated p21ras may simply be to cause Raf-1 to translocate to the membrane, after which other processes occur to activate the kinase. Also, under certain conditions Raf-1 dissociates from p21ras in detergent extracts of hormone-stimulated cells, while remaining activated.¹⁶⁷ Recent results indicate that Raf-1 phosphorylation and dephosphorylation correlate with active and less active forms of the enzyme, suggesting that the role of p21ras-mediated recruitment of Raf-1 to the membrane is to promote its phosphorylation and activation.³²³

Also, chaperone proteins such as 14-3-3 appear to be involved in the regulation of Raf-1 activity. The exact molecular events that lead to Raf-1 activation are still unclear, however.³²⁴

The substrate specificity of Raf-1 is quite limited and the only known cellular target is a protein kinase, MAP kinase (MEK). This kinase was first isolated as an activator of yet another protein kinase, the mitogen-activated protein kinase (MAPK). MEK is activated by phosphorylation on serines by Raf-1. Curiously, MEK phosphorylates MAPK at both a threonine and a tyrosine located in a Thr-Glu-Tyr motif. Thus MEK has the rather unusual property of being able to phosphorylate both an aliphatic and an aromatic amino acid. By mutational analysis and by selective dephosphorylation with protein phosphatases, phosphorylation of both the tyrosine and threonine has been demonstrated to be required for activation of MAPK.^{2,169-177} In the cell, activation of MAPK is transient even in the continued presence of insulin, and the time course is similar to that of p21ras activation.¹⁷⁸ Thus a cascade of phosphorylation and activation events occur with these kinases.^{2,169-177} Using dominant negative mutants of p21ras, the activation of this cascade by insulin has been shown to be dependent on p21ras function.

Although both Raf-1 and MEK have restricted substrate specificities, MAPK appears to phosphorylate numerous cellular targets. There are several isoforms of MAPK,^{2,169-177} but appreciable differences in substrate specificity have not been demonstrated. Interestingly, upstream signaling elements such as Sos, Raf-1, and MEK are phosphorylated by MAPK.^{179,180} This may constitute negative feedback mechanisms, but this idea awaits experimental confirmation. Many targets for MAPK are in the nucleus. In several systems, MAPK is targeted to the nucleus from the cytoplasm in response to external signaling factors, and this presumably constitutes an important mechanism by which extracellular signals regulate nuclear events.¹⁸¹⁻¹⁸⁴ The c-jun, c-myc, elk-1, and NF-IL6 transcription factors are phosphorylated and activated by MAPK.¹⁸⁵⁻¹⁹⁰ The activities of several enzymes are modulated by MAPK phosphorylation. Phospholipase A₂, which catalyzes the rate-limiting step in the synthesis of prostaglandins and leukotrienes, has been shown to be activated by MAPK phosphorylation.¹⁹¹ A tyrosine phosphatase, tyrosine phosphatase 2C, is deactivated by MAPK.¹⁹² MAPK also can activate two serine kinases, p90^{sk} and MAPKAP-2.^{193,194} At our current state of understanding, it seems likely that insulin action on the ras/MAP kinase pathway is related to regulation of transcription factors and nuclear events that mediate its effects on cell proliferation and perhaps other important processes through the regulation of protein expression levels.

CONCLUSIONS

Our overall understanding of the mechanisms of insulin action has been significantly extended over the past several years, leading to the identification and characterization of two important signaling pathways, p21ras/MAP kinase and PI-3-kinase/PDK1/Akt. Each of these pathways is initiated by the insulin receptor tyrosine kinase and downstream tyrosine-phosphorylated substrate proteins, which act as scaffolds for downstream signaling proteins. Each of these pathways also leads to switching of the signaling mode from tyrosine kinase (receptor) to protein serine/threonine kinases that act on target proteins to modulate cellular processes. In the case of the

p21ras pathway, it appears that the protein serine/threonine kinases may act primarily to modulate gene expression and cell proliferation, while the protein kinases downstream of the PI-3-kinase pathway acutely regulate a large number of metabolic processes as well as gene transcription. Classic insulin-sensitive pathways regulated by these latter protein kinases include glucose transport, glycogen synthesis, gluconeogenesis, and protein synthesis. A third insulin-signaling pathway involving CAP/c-Cbl/TC10 may also play a significant role in the regulation of glucose transport in fat and muscle, and will be an important topic for future investigation. Much work is required to clarify a number of details in connecting the protein kinases known to mediate insulin action to the proteins and processes they regulate. Furthermore, it is also recognized that protein serine/threonine phosphatase activity is involved in key insulin responses such as the activation of glycogen synthase. The underlying mechanisms of this regulation will also require substantial additional research to bring us to a full understanding of insulin action.

Incretins: Glucose-Dependent Insulinotropic Polypeptide and Glucagon-Like Peptide 1

David D'Alessio

THE INCRETIN EFFECT

Healthy humans have the capacity to ingest and efficiently assimilate large amounts of carbohydrate with relatively minor changes in circulating glucose concentrations. This precise control of glycemia despite widely varying intake is due in large measure to the rapid secretion of appropriate amounts of insulin after meals. Insulin secretion in response to eating is a complex process that is regulated by the interaction of substrate and neural and hormonal stimuli. The gastrointestinal (GI) tract plays an important role in the disposition of carbohydrate meals by secreting insulinotropic peptides that effectively connect substrate absorption to insulin secretion, a process that is critical for adjusting pancreatic β cell output to a given load of nutrients. These GI peptides were termed **incretins** by investigators in the early part of the last century to signify that they stimulated internal or endocrine secretions of the pancreas, in contrast to **excretins**, hormones that stimulated pancreatic exocrine secretion. Thus incretins represent one of the earliest classes of hormones to be described and their study, especially as they relate to normal and abnormal glucose tolerance, has a long history.¹

Although the presence of insulinotropic substances in the mucosa of the intestine had been known for many years, it was not until the advent of radioimmunoassay (RIA) and the ability to measure circulating insulin levels that the importance of incretins was clearly demonstrated. The observation that circulating insulin levels are significantly higher after glucose is ingested, compared to when it is administered intravenously (IV), was made by several groups and termed the **incretin effect**.^{2,3} Insulin secretion during progressively increasing oral glucose loads increases linearly, despite peak plasma glucose levels that vary only slightly. This indicates that plasma glucose levels *per se* constitute a relatively fixed proportion of the stimulus to the β cell, and this fraction becomes smaller as the load of ingested glucose increases (Fig. 6-1). Thus stimuli other than glucose effect the increase in meal-induced insulin release and influence the overall β -cell output. Incretin hormones, released in proportion to meal size, augment glucose-stimulated insulin secretion, a synergy that links insulin secretion to the quantity of ingested nutrients. When calculated as the difference between plasma insulin and/or C-peptide levels after oral glucose and isoglycemic IV glucose infusions, the incretin effect accounts for 30–60% of the β -cell output following glucose ingestion in healthy humans.^{2,4}

Beyond regulating the amount of insulin secreted during meal absorption, incretins prime the β -cell response to glucose, inducing

the rapid release of insulin characteristic of the normal postprandial response. The combination of stimuli activated by food ingestion triggers a brisk islet cell response that does not require, and in fact preempts, large increases in plasma glucose. The importance of a primed, rapid pattern of insulin release after eating is exemplified by studies of persons with impaired glucose tolerance (IGT) in whom a sluggish early insulin response to carbohydrate meals is associated with exaggerated glycemic excursions and late prandial hyperinsulinemia. The integrity of the incretin effect in IGT is not well characterized, but persons with type 2 diabetes mellitus (T2DM), have only a minimal augmentation of insulin release with oral versus IV glucose, constituting a marked impairment in the incretin effect⁵ (Fig. 6-2). Whether the abnormal incretin effect in persons with diabetes is due to specific abnormalities in the release or action of incretin hormones, or is simply another consequence of generalized β -cell dysfunction is a question presently under investigation. However, given the major contribution of the incretin effect to normal glucose tolerance, its loss undoubtedly contributes to the delayed and attenuated insulin secretion that is a hallmark of diabetes.

The two major characteristics used to define an incretin are: (1) that it is released following nutrient, particularly carbohydrate, ingestion and (2) that concentrations reached after meals stimulate insulin secretion.² There are currently two known hormones that meet these criteria: *glucose-dependent insulinotropic polypeptide (GIP)* and *glucagon-like peptide 1 (GLP-1)*. Recent studies suggest that both of these peptides are necessary for normal glucose tolerance. Consideration of incretins in relation to diabetes is timely because recent evidence raises the possibility that abnormalities of incretin function may contribute to the pathogenesis of diabetes. In addition, there are ongoing efforts to exploit the incretin pathways to treat diabetic patients. This chapter will review the physiology of the two major incretins, their integration into the insulin response to meals, and the relation of these peptides to the pathophysiology of diabetes.

GLUCOSE-DEPENDENT INSULINOTROPIC POLYPEPTIDE (GIP)

Brown and Pederson discovered and isolated GIP based on the ability of extracts of the porcine upper intestine to suppress gastric acid secretion in dogs.^{6,7} Originally called gastric inhibitory polypeptide, this 42-amino-acid peptide has significant homology

FIGURE 6-1. The incretin effect. Plasma concentrations of glucose (**top**) and C peptide (**bottom**) during 25-g (left), 50-g (middle), and 100-g (right) oral glucose loads (**filled circles**) and isoglycemic intravenous glucose infusions (**open circles**). Plasma glucose concentrations are similar for the three doses of oral glucose, demonstrating the precision of normal glucose homeostasis, and matched in each case by IV glucose, providing equivalent levels of glycemic stimulus during both sets of studies. Insulin secretion, as reflected by plasma C-peptide levels, is greater for oral glucose in comparison with intravenous glucose, and the magnitude of this difference increases with the dose of oral glucose. (Reprinted with permission from Nauck et al.⁴)

CONTROL

TYPE 2 DM

FIGURE 6-2. Reduced incretin effect in subjects with type 2 diabetes. Plasma glucose (**top**) and C peptide (**bottom**) concentrations in persons with type 2 diabetes, and nondiabetic controls, during 50-g glucose ingestion (**filled circles**) and glucose infusions to glycemic levels matching those following oral glucose (**open circles**). In the control subjects insulin secretion, as reflected in plasma insulin and C peptide levels, is substantially greater following oral compared to IV glucose. However, in the diabetic subjects there is no difference overall in the integrated insulin and C peptide responses during oral and IV glucose loading. (Reprinted with permission from Nauck et al.⁵)

with peptides in the secretin family of regulatory peptides and the sequence is highly conserved across mammalian species, suggesting an important physiologic role.⁷ Soon after the structure of GIP was elucidated, the peptide was demonstrated to augment glucose-stimulated insulin secretion, and once specific RIAs became available to measure GIP in plasma, it became apparent that GIP is secreted into the circulation after meal consumption.^{1,6} Based on these findings, GIP was classified as an incretin and subsequent work indicates that this is the primary function of this hormone, while a physiologic role in the regulation of gastric function has not been clearly demonstrated. For these reasons the peptide was renamed glucose-dependent insulinotropic polypeptide.

Distribution, Synthesis, and Secretion of GIP

GIP is synthesized by endocrine K cells that are most prevalent in the mucosa of the duodenum and upper jejunum, and these cells are the only known source of GIP in humans.⁶⁻⁸ The GIP gene encodes preproGIP, a prohormone that is processed into the bioactive molecule.⁷ The nucleic acid and protein sequences of GIP are highly conserved across mammalian species, with homology of 40 of the 42 amino-acid residues between the human and porcine peptides, and a similar degree of homology between rats and humans.^{6,7} Expression

of the GIP gene is stimulated by oral glucose or enteral infusion of lipid in rats,⁷ and the effect of glucose to increase proGIP mRNA is also seen in an intestinal cell line,⁹ suggesting that direct contact of nutrients with the K cells stimulates GIP synthesis. Rats made diabetic by injection of streptozocin have increased intestinal GIP mRNA and peptide levels relative to control animals, indicating that GIP synthesis may be increased in diabetes.¹⁰

Ultrastructural examination of K cells reveals the characteristic intracellular secretory granules that typify endocrine cells. Indeed, GIP secretion occurs in a regulated manner and enteral nutrients are the primary stimulus. Both carbohydrate and lipids are potent activators of K-cell secretion, while the observed response to protein ingestion or amino acids in the gut has been more variable. Importantly, intravenous delivery of glucose, amino acids, or lipids does not stimulate GIP release, indicating that luminal interaction of substrates with the gut mucosa is critical for this process.^{6,7} GIP secretion in response to enteral glucose is proportional to the amount of glucose administered¹¹ and is dependent on the absorption of glucose by the intestinal mucosa.^{6,7} Schirra and colleagues demonstrated that following ingestion of a glucose-containing drink, GIP was released throughout the entire period of gastric emptying and ceased only after delivery of glucose to the duodenum was complete (left panels of Fig. 6-3).¹¹ Carbo-

FIGURE 6-3. Secretion of incretin hormones in response to oral and intraduodenal glucose. GLP-1 and GIP secretion in response to 50 g (solid symbols) and 100 g (open symbols) of oral glucose are shown in the top two panels. Plasma levels of the incretins increase rapidly following glucose ingestion and the concentrations of GIP and GLP-1 are more elevated in response to the larger dose of glucose. The lower panel shows plasma levels of GLP-1 and GIP in response to different rates of intraduodenal glucose. The release of GIP shows a dose-response relationship with the amount of glucose infused, while the pattern of GLP-1 release suggests a threshold of glucose delivery required to initiate secretion. (Reprinted with permission from Schirra et al.¹¹)

hydrate-stimulated GIP release is inhibited by pharmacologic inhibition of α -glucosidases, which limits glucose absorption in the upper gut, and phlorhizin, an inhibitor of mucosal glucose transport.² Sucrose and galactose also stimulate GIP release, while fructose does not.¹²

Stimulation of GIP release by triglycerides is dependent on intraluminal hydrolysis, absorption of fatty acids, and the packaging of reesterified triglycerides into chylomicrons.^{2,6} GIP release in response to fat increases with the quantity of lipid ingested, and fat is a more potent stimulus of GIP than glucose on a per-gram basis.¹³ It is likely that the mechanisms of glucose- and lipid-induced GIP secretion are distinct, and possibly derived from separate populations of cells.^{2,7} Consistent with this observation, the addition of fat to a glucose meal greatly accentuates the GIP response. Taken as a whole, the available data indicate that GIP secretion is regulated directly by the products of meal digestion in a dose-dependent manner. This supports the concept advanced by Ebert and Creutzfeldt that GIP acts as a quantitative signal of nutrient absorption to the endocrine pancreas.¹²

Following release into the circulation, GIP is metabolized by the enzyme dipeptidyl peptidase IV, a ubiquitous protease that cleaves specifically between residues 2 and 3, leaving GIP-[3-42].^{7,14} This conversion occurs rapidly, so that the circulating half-life of full-length GIP is only several minutes, and is inactivating because GIP[3-42] does not stimulate insulin secretion.

Signaling Through the GIP Receptor

A single GIP receptor has been identified and is currently believed to mediate all of the physiologic effects of the peptide. The GIP receptor has seven-transmembrane domains and substantial homology with receptors in the secretin-VIP receptor family, particularly the glucagon and GLP-1 receptors.^{8,15,16} The GIP receptor is expressed in both α and β cells of the pancreatic islet,¹⁷ the upper GI tract, adipocytes, adrenal cortex, pituitary, and a variety of brain regions.⁸ Both full-length GIP[1-42] and several GIP congeners, truncated at the N- and C-terminus bind to the GIP receptor with high affinity, but none of the related peptides from the glucagon family interact with this receptor.^{7,15}

Ligand binding to the GIP receptor activates adenylyl cyclase through stimulatory GTP-binding proteins and GIP induces dose-dependent increases in intracellular cyclic AMP.^{15,16} The potentiation of glucose-, and depolarization-stimulated exocytosis from β cells by GIP is mediated primarily via the protein kinase A signaling pathway.¹⁸ There remains some question as to whether or not GIP also acts through other signaling pathways in the β cell, and the details of the intracellular effects of incretins is an active area of ongoing research.

Recent work demonstrates that the GIP receptor is susceptible to homologous desensitization.^{10,19,20} Both *in vitro*, as well as in intact animals, extended exposure to GIP attenuates the insulinotropic effect of the peptide. The mechanism for agonist-mediated desensitization of the GIP receptor is multifactorial and involves both uncoupling of the receptor from G proteins and an increased turnover of activated G proteins. Ligand-induced desensitization of the GIP receptor, in the context of the increased circulating GIP levels reported by many groups to occur in type 2 diabetic subjects (see below), has been advanced as an explanation for the diminished incretin effect seen in diabetes.

The Incretin Function of GIP

GIP is insulinotropic in the presence of glucose concentrations greater than 5–6 mmol.^{2,6} This action has been demonstrated in a broad range of experimental models including cell lines, cultured pancreatic islets, isolated perfused pancreas, and a variety of animals. In humans both porcine and synthetic human GIP stimulate insulin secretion when infused to concentrations mimicking those occurring after meals. A key point is that GIP-stimulated insulin secretion occurs only when glucose levels are elevated above fasting. This glucose dependence is common to most endogenous insulinotropic peptides and neurotransmitters, and functionally serves as protection against hypoglycemia. The tight coupling of GIP secretion to glucose absorption by the gut, the potency of postprandial concentrations of peptide, and the dependence of GIP action on the ensuing hyperglycemia have become the hallmarks of incretin physiology.

Beyond the fact that infusions of GIP to humans in amounts estimated to be physiologic augment glucose-stimulated insulin release, the role of GIP as an incretin has been demonstrated by several classic experimental methods in rodents. Removal of circulating GIP with a specific antiserum abolished the insulinotropic effect of exogenous GIP and caused glucose intolerance with diminished insulin secretion during enteral glucose loading.^{2,6} Similarly, administration of GIP[7-30 amide], a competitive antagonist of the GIP receptor, significantly attenuated the insulin response to a typical meal.²¹ Most recently, a line of mice was created with a targeted gene deletion of the GIP receptor.²² These animals had normal fasting glucose and insulin levels and responses to intraperitoneal glucose loads that were comparable to wild-type control mice. However, in response to oral glucose loading the GIP-receptor-knockout mice had significant glucose intolerance and impaired insulin secretory responses (Fig. 6-4). Interestingly, when these animals were made insulin-resistant by chronic feeding of a high-fat diet, their glucose intolerance worsened, in contrast to high-fat-fed control mice that maintained normal glycemic excursions following oral glucose. This experiment demonstrated that absence of the GIP receptor impairs the normal augmentation of insulin secretion induced by insulin resistance. Taken together, these studies in rodents indicate that the incretin action of GIP is necessary for normal glucose tolerance and suggest that GIP may play a role in adapting insulin secretion to changes in insulin sensitivity.

Other Effects of GIP

The GIP receptor is expressed on pancreatic α as well as β cells, but the role of GIP in the control of glucagon secretion is not clear. GIP stimulates exocytosis in isolated rat α cells²³ and increases glucagon release from the isolated perfused pancreas.⁶ However, in humans infusion of GIP does not change plasma glucagon concentrations significantly.²⁴ It is possible that other effects of GIP, such as stimulation of insulin release, counteract direct effects to stimulate the α cell. Regardless, current information indicates that there is little overall effect of GIP on glucagon levels *in vivo*.

The GIP receptor is expressed in adipose tissue and evidence exists to suggest that GIP has regulatory effects on lipid metabolism.^{7,25} In isolated adipocytes or adipocyte cell lines, GIP potentiates the effects of insulin to promote glucose uptake and augment lipogenesis, inhibits glucagon-stimulated lipolysis, and increases lipoprotein lipase activity.²⁵ In animals, GIP administration promotes the clearance of postprandial triglyceride-rich lipoproteins.

Thus the hypothesis that GIP, synthesized and secreted in response to ingested fat, plays an important role in lipid anabolism has some support in animal studies.²⁵ However, a physiologic role for GIP to regulate lipid metabolism in humans has yet to be convincingly demonstrated.

Since GIP was initially isolated based on its activity to inhibit acid secretion in denervated gastric pouches, it is ironic that an important physiologic role for GIP in gastric function has yet to be demonstrated.^{6,7} It is possible that GIP contributes to the suppression of gastric acid secretion that occurs after consumption of a fat meal. The most likely mechanism for decreased acid production is via stimulation of gastric somatostatin release.^{6,7} Recently GIP has been shown to increase intestinal glucose transport during enteral glucose infusion in isolated rat intestine,²⁶ a finding that was confirmed in intact rats by administration of a GIP antagonist that inhibited glucose transport relative to controls.²⁷ These results suggest a broad role for GIP to increase glucose metabolism by increasing both substrate absorption and disposition through its actions on the gut and pancreatic islet.

GIP in Diabetes

Because GIP plays an important role in the normal physiology of insulin secretion after nutrients are ingested, a number of investigators have considered whether or not abnormalities in GIP secretion or action contribute to glucose intolerance or diabetes. There have been important incongruities among some of these studies and it is not likely that GIP has a prominent role in the pathogenesis of glucose intolerance and diabetes in humans. However, when all the evidence is considered, a plausible case can be made that abnormalities in the GIP axis contribute to the impaired incretin effect in at least some diabetic subjects.

It is unlikely that GIP is involved in the metabolic abnormalities seen in type 1 diabetes. In newly diagnosed patients with T1DM, GIP secretion after meals is lower than in nondiabetic controls but returns to normal over several months.¹³ However, in neither newly diagnosed patients nor individuals with longstanding type 1 diabetes is there a correlation between GIP concentrations in the plasma and β cell function. Type 1 diabetic subjects retaining some insulin secretory capacity respond to exogenous GIP, but have subnormal responses relative to controls, in all likelihood due to decreased islet mass and abnormal β -cell function. The molecular species of GIP found in diabetic patients are qualitatively comparable to controls, and there seems to be no effect of glycemic control or intensity of insulin treatment on the GIP response to ingested nutrients in persons with T1DM. Based on these data, the notion that K-cell secretion of GIP is regulated in a feedback manner by insulin, as had been suggested previously, seems doubtful.

Many studies have found that persons with type 2 diabetes have increased plasma concentrations of GIP following glucose or meal ingestion, compared with nondiabetic individuals.^{12,13} However, GIP hypersecretion has not been a uniform finding in diabetic subjects,^{13,24} and there is no obvious explanation for this discrepancy among studies. It is plausible that increased meal-induced GIP secretion occurs only in subgroups of diabetic individuals, a possibility suggested by several studies including large numbers of subjects.^{12,13} Studies of nondiabetic obese subjects indicate that obesity *per se* does not alter postprandial GIP levels or clearance of GIP, and GIP does not seem to contribute to the hyperinsulinemia seen in obese persons.^{28,29} Similarly to subjects with type 1 diabetes, neither glycemic control nor treatment with insulin or oral

agents affects nutrient-stimulated GIP in type 2 diabetic patients.^{29,30} Thus there is no clear explanation for the common finding of augmented secretion of GIP after meals in at least a substantial proportion of diabetic individuals. A recent examination of healthy first-degree relatives of type 2 diabetic patients demonstrated that integrated GIP release over 24 hours, including three meals, was increased by 20–25% relative to persons with no family history of diabetes.³¹ These findings suggest that changes in GIP secretion may precede the onset of impaired glucose tolerance, and raise the possibility that increased incretin secretion could develop to compensate for early β -cell dysfunction.

Several studies have assessed the insulinotropic effect of GIP in type 2 diabetes using infusions of synthetic human GIP. Overall these studies demonstrate that GIP increases glucose-stimulated insulin secretion in diabetic subjects but the relative magnitude of this response is significantly less than that of control subjects.^{13,24} For example, Nauck and colleagues found that in a group of well compensated type 2 diabetic subjects the incremental C-peptide response to GIP during a hyperglycemic clamp was only 46% of the response seen in nondiabetic individuals.²⁴ However, in a small study of diabetic subjects with more severe β -cell defects, the insulinotropic effect of GIP was completely absent.³² Interestingly, several point mutations of the GIP receptor have been discovered, some of which diminish GIP-stimulated cyclic AMP generation,^{33,34} and it has been suggested that this might account for a decreased GIP effect in diabetic subjects. However, the frequency of these mutant forms is not different among type 2 diabetic and nondiabetic subjects, and so is unlikely to explain any general impairment of the incretin function of GIP among subjects with diabetes. The important issue is whether an impaired response to GIP is a specific defect of the diabetic β cell, or simply another manifestation of the overall insulin secretory defects seen in diabetic patients. While one group of investigators has calculated “normal” sensitivity to GIP of diabetic subjects when considered in the context of generalized β -cell dysfunction, this remains an undecided question.³⁵ Interestingly, it appears that islet sensitivity to GIP is decreased in older humans, and it has been suggested that this may contribute to glucose intolerance seen with aging.³⁶

GLUCAGON-LIKE PEPTIDE 1 (GLP-1)

When the structure of proglucagon (ProG) was determined in the early 1980s, it became apparent that peptides other than glucagon were produced from this prohormone. Based on the nucleotide and amino acid sequence of ProG, the glucagon-like peptides GLP-1 and GLP-2 were deduced. GLP-1 has significant sequence homology to glucagon but a very different physiologic role. Like GIP, GLP-1 is secreted after meals and is a potent stimulus to glucose-stimulated insulin secretion. Recent studies have proven that GLP-1 has a physiologic role as an incretin. Moreover, administration of this peptide to persons with type 2 diabetes causes marked improvements in insulin secretion and glucose disposition, raising the possibility that GLP-1 or analogues could be useful in the treatment of these patients.

Distribution, Synthesis, and Secretion of GLP-1

In humans, proglucagon is synthesized by pancreatic α cells, L cells located in the intestinal mucosa, and a population of neurons located in the hindbrain.^{1,37,38} These cells all transcribe identical

ProG mRNA that is translated to a common prohormone (see Chap. 7). Processing of ProG in the pancreatic islet yields glucagon with little production of GLP-1, while L cells make GLP-1, GLP-2, and virtually no glucagon.^{1,38} This tissue-specific processing of ProG is due at least in part to the presence of prohormone convertase 1 (PC1/3) in L cells, but not α cells, since PC1/3 cleaves GLP-1 from ProG.³⁷ Within the ProG molecule, putative dibasic cleavage sites occur on either end of the 37-amino-acid moiety GLP-1[1–37]. However, L cells process ProG almost entirely into the truncated peptides, GLP-1[7–36 amide] and GLP-1[7–37], and these are the species for which biologic activity has been demonstrated. In humans and other mammals, approximately 80% of intestinally derived GLP-1 is the amidated form, GLP-1[7–36 amide].

In contrast to the GIP-producing K-cells located most prominently in the duodenum and upper jejunum, L cells are most prevalent in the lower gut. On average, 70–90% of the intestinal GLP-1 is synthesized in the lower jejunum, ileum, and colon.¹ GLP-1 levels in the circulation increase after ingestion, but not IV infusion, of nutrients.^{11,39,40} Like GIP, glucose and lipids are the most potent stimuli to GLP-1 release, with some question as to whether or not protein or amino acids are stimulatory. Unlike GIP, the release of GLP-1 does not seem to be dependent on nutrient absorption in the intestine, but appears to be linked to the rate at which nutrients are delivered to the gut (left panels of Fig. 6-3).¹¹

Despite the marked difference in the distribution of the two peptides along the gut, secretion of GLP-1 and GIP after mixed or glucose meals occurs in parallel (Fig. 6-3).^{11,40} The rapid release of GLP-1 in response to food intake is somewhat paradoxical in light of the distal location of the majority of L cells and raises questions as to the mechanism of nutrient-stimulated GLP-1 secretion. One possibility is suggested by the observation that in rats, increased ProG synthesis in response to refeeding after a fast seems to be localized to upper but not lower intestinal L cells.⁴¹ From these data it could be inferred that in fact nutrient-stimulated GLP-1 secretion may be accounted for by the minority of L cells in the upper gut. Alternatively, there is evidence that a neural pathway from the upper to lower gut mediates GLP-1 release,³⁷ and it appears that vagal cholinergic and peptidergic signaling contributes to the coupling of intestinal nutrients with GLP-1 secretion in rats. This finding is supported by one study in healthy humans given cholinergic blocking agents,⁴² and another showing a normal GLP-1 response of subjects with proximal ileostomies, in whom the majority of L cells do not come in contact with luminal nutrients.⁴³ However, GLP-1 secretion is normal, or even accentuated, in subjects with total gastrectomy and surgical disruption of the abdominal vagi.⁴⁴ So, while there are several aspects of nutrient-stimulated GLP-1 secretion to suggest neural coupling, the specific pathways involved are not clear. Interestingly GIP has been shown to evoke GLP-1 secretion in several *in vitro* models,³⁷ suggesting that GIP could act as a humoral stimulus of GLP-1 release. However, in humans IV infusions of even supraphysiologic amounts of GIP do not increase plasma GLP-1 concentrations.⁴⁵ A recent examination of the canine gut indicates that there is substantial overlap among GIP-secreting K cells and L cells, with a high frequency of jejunal L cells immediately adjacent to K cells.⁴⁶ This finding presents the possibility of paracrine stimulation of GLP-1 secretion by GIP as an alternative to nutrient-, endocrine-, or neurally-mediated mechanisms. Despite the interesting possibilities suggested by studies addressing the mechanism(s) of nutrient-stimulated GLP-1 secretion, this issue remains an open and important question. Efforts to

understand the process of GLP-1 release are driven by the possibility that factors enhancing endogenous release of the peptide could be useful in stimulating insulin secretion and promoting glucose tolerance in diabetes.

Similarly to GIP, GLP-1 is rapidly metabolized in the circulation by dipeptidylpeptidase (DPP) IV.¹⁴ This enzyme is present on capillary endothelial cells located diffusely throughout mammalian tissues and in plasma. DPP IV cleaves the N-terminal His-Ala from GLP-1[7–36 amide] leaving GLP-1[9–36 amide], and this process occurs with a half-life of approximately 1–2 minutes for intact GLP-1 in mammalian plasma.^{1,37} Because the N-terminus of GLP-1 is essential for its insulinotropic effect, metabolism by DPP IV likely inactivates this action. In fact GLP-1[9–36 amide] may be a competitive antagonist of the GLP-1 receptor, an effect that has been reported both *in vitro* and *in vivo*.¹ GLP-1[9–36 amide] is renally cleared with a half-life of approximately 5–10 minutes, so it is the primary circulating GLP-1 species in the postprandial circulation.⁴⁷

Signaling Through the GLP-1 Receptor

A specific GLP-1 receptor was cloned from pancreatic islet cells^{1,37} and is the only known mediator of GLP-1 signaling in mammals. The mRNA for this receptor has been unequivocally demonstrated in specific regions of the brain, stomach, and lung, as well as pancreatic β cells. Additionally, some investigators have reported that the GLP-1 receptor is synthesized by islet α cells, hepatocytes, skeletal muscle cells and renal parenchymal cells, but these findings have not been uniform. Binding of radiolabeled GLP-1 to adipocytes, and the expression of the GLP-1 receptor in a preadipocyte cell line suggests that fat tissue also contains specific GLP-1 binding sites.

Like the GIP receptor, the GLP-1 receptor is a member of the secretin-VIP family of seven-membrane-spanning, G-protein coupled receptors. Ligand binding by this receptor is highly specific and there is little affinity for glucagon or GIP. However, exendin-4 and exendin[9–39], peptides homologous to GLP-1 found in the venom of the Gila monster (*Heloderma suspectum*), are a naturally-occurring GLP-1 receptor agonist and antagonist, respectively.⁴⁸ Similarly to GIP, GLP-1 mediates its effects on the β cell through activation of adenylyl cyclase and formation of intracellular cyclic AMP. Foremost among these effects are: synergism with glucose to close K_{ATP} channels, augmentation of glucose-induced increases in intracellular calcium, and promotion of secretory granule exocytosis at a site distal to the elevation of intracellular calcium.⁴⁹ While protein phosphorylation by protein kinase A (PKA) is central to the intracellular transmission of the GLP-1 signal, recent work indicates that PKA-independent processes are also important.⁵⁰

Ligand binding leads to internalization and degradation of the GLP-1 receptor. There is evidence from studies of β -cell lines and normal islets in culture that the GLP-1 receptor also undergoes homologous and heterologous desensitization since protracted incubation with GLP-1, or activation of the protein kinase C pathway, decreases generation of cyclic AMP and downstream effects of the peptide. It has been suggested that overlapping desensitization through signaling pathways that promote β -cell secretion acts as a means of preventing excessive insulin release.⁵¹ However, it is unclear what role ligand-induced desensitization has *in vivo*, or whether this effect would lead to tachyphylaxis in the presence of prolonged elevations of circulating GLP-1.

Incretin Actions of GLP-1

Administration of GLP-1 to animals and humans increases insulin secretion during hyperglycemia (right panels of Fig. 6-4),^{1,39} and this effect occurs at concentrations of GLP-1 that are similar to those observed in the circulation after meals. Similarly to GIP, the insulin stimulatory effect of GLP-1 is glucose-dependent and is substantially diminished at glucose levels less than 5.5 mmol. The effect of GLP-1 to promote insulin release is additive to that of GIP, suggesting that the two incretin hormones act together in regulating postprandial insulin secretion.⁴⁵

In addition to acting as an acute insulin secretagogue, GLP-1 has several other actions that enhance the release of insulin. GLP-1 increases insulin biosynthesis, and stimulates the transcription of other β -cell genes including glucokinase and the GLUT-2 glucose transporter.^{37,52} Exendin-4, a GLP-1 receptor agonist, induces β -cell neogenesis and expansion in rats.⁵³ Finally, GLP-1 increases the capacity of individual β cells to respond to stimulation by glucose, and this effect to activate glucose-insensitive cells has been termed induction of glucose competence.¹ Taken together, these findings suggest a broad role for GLP-1 to promote β -cell function.

Several recent reports have conclusively established a role for GLP-1 as a physiologic incretin. Rats given exendin[9–39], a specific GLP-1 receptor antagonist, during enteral glucose feeding had increased postmeal glycemia coincident with attenuated insulin release, compared to control animals.¹ Similar results were reported in nonhuman primates given either exendin[9–39] or an anti-GLP-1 monoclonal antibody, and in these studies interference with the action of GLP-1 caused a rightward shift in the insulin response curve such that insulin secretion was decreased during the early phases of nutrient absorption, but rose later in the study, possibly in response to the higher levels of glucose.⁵⁴ Consistent with these findings, male mice with a targeted gene deletion of the GLP-1 receptor have abnormal glucose tolerance and attenuated insulin release after glucose ingestion⁵⁵ (Fig. 6-4). Interestingly, these animals have increased circulating levels of GIP and an accentuated insulin secretory response to GIP,⁵⁶ raising the possibility that the incretin effect is part of a closed-loop regulatory system. Thus substantial experimental evidence demonstrates an important role for GLP-1 in mediating the insulin response to meals, and indicates that this gut peptide is necessary for normal glucose tolerance.

FIGURE 6-4. Glucose tolerance (top) and insulin secretion (bottom) in mice with targeted gene deletions of the GIP (left panel) and GLP-1 (right panel) receptors. GIP-receptor-knockout mice (solid squares) have an increased glucose excursion during oral glucose loading compared to control mice (open circles). Despite the increased plasma glucose levels, insulin secretion in the mice lacking the GIP receptors (black bars) is lower than controls (white bars). The GLP-1-receptor-knockout mice (solid squares) also have impaired glucose tolerance following oral glucose administration compared to control animals (open circles). Similarly to the GIP knockouts there is a decrement in insulin secretion during the oral glucose tolerance test (GLP-1_r -/- hatched bars) (controls black bars). These data demonstrate that signaling through both the GIP and GLP-1 receptors is necessary for a normal incretin effect, with appropriate insulin secretion and glucose tolerance in response to enteral glucose. (Reprinted with permission from Miyawaki et al²² and Scrocchi et al.⁵⁵)

In addition to abnormalities in the insulin and glucose responses to ingested glucose, GLP-1-receptor-deficient mice have fasting hyperglycemia and impaired insulin secretion in response to parenteral glucose.⁵⁵ While this latter finding is puzzling at first glance since an incretin factor should be secreted and act during nutrient absorption, recent studies *in vitro*,⁵⁷ and in humans,⁵⁸ suggest that basal levels of GLP-1 may play a role in β -cell function. The observation that GLP-1 receptor knockout mice have decreased pancreatic insulin and insulin mRNA content⁵⁶ is also consistent with the notion that basal, or unstimulated levels of GLP-1 have important effects on β -cell function. These cumulative data suggest that GLP-1 may have important effects on insulin biogenesis and release beyond its action as an acute secretagogue.

Other Actions of GLP-1

Similarly to GIP, GLP-1 has been shown to have effects on tissues other than the pancreatic β cell. In general, these possible alternative functions of GLP-1 have not been as conclusively established as are the effects of the peptide as an insulin secretagogue. Nonetheless, these extrainsular effects of GLP-1 involve other processes in the regulation of nutrient, particularly carbohydrate, metabolism, and so are consistent with the known incretin function of the hormone. Therefore a reasonable case can be made that GLP-1 has a broad physiologic role in minimizing fluctuations in blood glucose levels.

In contrast to GIP, GLP-1 lowers fasting and postprandial glucagon concentrations in humans and animals.^{1,39} Of note, only a minority of α cells expresses the GLP-1 receptor,⁵⁹ and among these cells relative expression is lower than that of the GIP receptor.¹⁷ Similar to findings *in vivo*, GLP-1 stimulates insulin secretion and inhibits glucagon release from isolated human islets.⁶⁰ However, GLP-1 has little effect on glucagon secretion from cultured α cells from disrupted islet cell preparations, and actually stimulates glucagon release from isolated, purified α cells.²³ The different responses to GLP-1 in animals and intact islets compared to isolated α cells imply that paracrine actions of insulin and/or somatostatin are the primary mechanisms by which GLP-1 regulates glucagon secretion. Similarly to the β cell, the α cell seems to be tonically regulated by GLP-1 since glucagon levels increase when the GLP-1 receptor antagonist exendin[9–39] is administered in the fasting state when GLP-1 is at basal levels.^{54,58} With the addition of a glucagonostatic effect to its incretin action, GLP-1 can be seen as coordinating the secretion of islet hormones in the postprandial state to restrain elevations in blood glucose.

Doses of GLP-1 estimated to mimic postprandial plasma concentrations inhibit antral contractions, increase pyloric tone, and substantially lower the rate of gastric emptying of both liquid and solid meals.⁶¹ This effect is sufficient to minimize the rise in meal-induced glucose and insulin levels. Supraphysiologic doses of GLP-1 virtually abolish gastric emptying. The effects of GLP-1 on gastric motility, as well as its inhibition of gastric acid secretion, are likely mediated through vagal afferent signals emanating from nerve terminals in the gastrointestinal lining.^{62,63} While it is likely that regulation of gastric function is a normal part of the physiologic action of GLP-1, this has not been proven. In nonhuman primates given the GLP-1 receptor antagonist exendin[9–39] during oral glucose tolerance tests, no difference in delivery of carbohydrate to the intestine was noted,⁵⁴ suggesting that with small liquid meals the effect of GLP-1 to slow gastric emptying may be small.

Administration of GLP-1 into the cerebroventricular system of rats decreases food intake⁶⁴ raising the possibility that this incretin may also play a regulatory role in satiety or body weight regulation. Short-term infusion of GLP-1 to humans suppresses consumption of a subsequent lunch^{65,66} suggesting that the satiety effects of GLP-1 are mediated by peripherally, rather than centrally, derived peptide. It is possible that effects of GLP-1 on food intake are mediated through the same neural circuits that regulate gastric emptying. Currently there is some debate as to whether or not long-term administration of GLP-1 causes weight loss, and this remains an important question for future investigation.

Several reports suggest that GLP-1 increases glucose disposal independent of its effects on islet hormones. In type 1 diabetic subjects infused with constant rates of IV insulin, the amount of glucose required to maintain euglycemia was 15–20% higher when GLP-1 was also given, suggesting that GLP-1 increased glucose disposal independent of changes in insulin concentration.⁶⁷ Subsequently, it was shown that infusions of GLP-1 increased the rate of glucose disappearance in healthy subjects given IV glucose, and that this effect was due to increases in both insulin secretion and glucose effectiveness, an index of insulin-independent glucose disposition.⁶⁸ No specific process has yet been discovered to explain these findings, although it appears that GLP-1 does not affect insulin sensitivity in humans.^{68,69} *In vitro* studies indicate that GLP-1 can increase glucose transport in adipocytes and preadipocytes,^{70,71} and promote glycogen synthesis in both muscle and hepatocyte preparations.¹ However, to date none of the *in vitro* and *in vivo* results have been corroborated in a manner that provides a mechanism for these actions of GLP-1. Therefore, the physiologic importance of extra-islet effects of GLP-1 on glucose metabolism remains controversial.

GLP-1 in Diabetes

Because of its importance for glucose tolerance, and because diabetic persons appear to have a defective incretin augmentation of insulin secretion, the adequacy of GLP-1 secretion in type 2 diabetes has been examined in several studies. While some groups have suggested that GLP-1 secretion is increased in type 2 diabetes,^{72,73} others have come to the opposite conclusion, that GLP-1 secretion is impaired in diabetic individuals.⁷⁴ These studies have used different assays of plasma GLP-1, so the lack of consensus may be due to technical discrepancies. However, it seems more likely that these differences are the result of the relatively small sample sizes studied with distinct characteristics that could independently affect the results. For example, it is not clear whether obesity, antidiabetic treatment, or duration of diabetes alters GLP-1 secretion; but any of these (or other parameters) could confound the results of a small study. Given that GLP-1 secretion has not been consistently observed to be impaired in diabetic subjects, it is probably safe to conclude that decreased release of this incretin does not play an etiologic role in the vast majority of cases of T2DM. This conclusion is supported by the fact that nondiabetic, but high-risk, members of families with diabetes have normal GLP-1 secretion.³¹

GLP-1 improves hyperglycemia, sometimes dramatically, in diabetic subjects, and this is due in great part to its effects on the release of the islet hormones. Continuous IV administration of GLP-1 to poorly controlled type 2 diabetic patients decreased blood glucose concentrations to near normal levels within 3–4 hours,

FIGURE 6-5. Plasma glucose concentrations in type 2 diabetic subjects infused with saline (open circles), or GLP-1 (filled circles). Values from untreated control subjects are also shown (open diamonds). Administration of GLP-1 rapidly lowered fasting glucose to normal levels in the diabetic subjects, and greatly improved glucose tolerance with meal ingestion. (Reprinted with permission from Rachman et al.⁷⁹)

coincident with increased insulin and decreased glucagon levels.⁷⁵ In addition, fasting hyperglycemia was significantly improved in a group of type 1 diabetic subjects with minimal insulin secretory reserve given IV GLP-1, most likely due to suppressed glucagon secretion.⁷⁶ However, the most prominent effect of GLP-1 in diabetic individuals is stimulation of the β cell. Even in low doses GLP-1 improves the responsiveness of the β cell to glucose in persons with impaired glucose tolerance,⁷⁷ an effect that may pertain to persons with mild diabetes as well.⁷⁸ Pharmacologic doses of GLP-1 are almost uniformly insulinotropic in subjects with type 2 diabetes,^{24,79} in marked contrast to the relative ineffectiveness of GIP to stimulate insulin release in this population. Continuous IV administration of GLP-1 to persons with T2DM normalized fasting and postprandial glucose levels for nearly a full day (Fig. 6-5).⁷⁹ That this effect was due primarily to improvements in insulin secretion is supported by a recent study demonstrating that GLP-1 did not change insulin-independent glucose disposal in diabetic persons.⁸⁰

The principal mechanism(s) by which GLP-1 exerts insulinotropic effects in diabetic subjects is not clear. Furthermore, it is not known why GLP-1, but not GIP, retains these properties in people with T2DM given the similarities in intracellular cell signaling between the two incretins. In aged rats with glucose intolerance, 48 hours of GLP-1 administration increased the expression of several genes—proinsulin, glucokinase, and the GLUT-2 glucose transporter—that are important in β -cell function.⁵² In this study there was an associated increase in the rapidity and magnitude of the insulin response that corrected the glucose intolerance of these aged animals. This suggests that some of the effects of GLP-1 to improve dysfunctional insulin secretion may result from stimula-

tion of the synthesis of key proteins. Understanding the processes through which GLP-1 renews insulin secretion in persons with diabetes is likely to provide important insights into the pathology of the β cell in this condition and as well as generating targets for novel therapeutics.

Because of the potent effects of IV GLP-1 in improving blood glucose levels in persons with diabetes, there has been much interest in using this peptide or an analogue in treating these patients. One major advantage of GLP-1 over many of the currently available agents used in treating diabetes is that its insulinotropic effect is glucose-dependent and so hypoglycemia is not likely to be a major side effect. GLP-1 has been administered to diabetic patients by subcutaneous injection before meals to decrease postprandial blood glucose excursions,^{81,82} but the doses used in these studies were pharmacologic and most likely caused significant inhibition of gastric emptying, sometimes associated with symptoms of nausea. Buccal preparations containing GLP-1 have also been shown to deliver peptide to the circulation and represent another potential mode of administration.⁸³ However, the problem with both subcutaneous and buccal delivery of GLP-1 is that because of the rapid metabolism of the peptide by DPP IV, the effects are short-lived. Continuous subcutaneous infusion of GLP-1 via a portable pump to subjects with type 2 diabetes caused significant improvements in their glycemic levels for up to 1 week and was well tolerated.⁸⁴ Several approaches to minimize the metabolism of GLP-1 to GLP-1[9–36 amide] and extend its time of action are currently being pursued.⁸⁵ DPP IV-resistant analogues of GLP-1 have been given to animals and shown to have increased potency compared to the native peptide. Additionally, DPP IV inhibitors

are available and have been used to augment the effectiveness of endogenous GLP-1. Other means of harnessing GLP-1 receptor signaling to improve glucose homeostasis include the use of longer acting or more potent parenteral analogues of GLP-1,⁸⁶ and genetically-engineered cells that can continuously secrete GLP-1.⁸⁷ These strategies, and the possibility of developing orally active GLP-1 receptor activators, are under current investigation.

OTHER INSULINOTROPIC PEPTIDES

Several other peptides synthesized in the GI tract affect β -cell function and have been examined for physiologic roles in meal-induced insulin secretion.^{2,88} Among these, cholecystokinin (CCK), gastrin, and secretin are secreted after food ingestion, are insulinotropic, and have clear endocrine functions, and so received significant attention as potential incretins. The CCK_A receptor is present on pancreatic islets and CCK increases insulin secretion *in vitro*. However, in humans, nutrient protein and fat, and not glucose, are the primary stimulus to CCK release, making it an unlikely candidate to mediate glucose-stimulated insulin secretion. Furthermore, CCK is not insulinotropic in humans when given in physiologic amounts and administration of CCK receptor antagonists does not alter postprandial insulin levels in healthy humans. Interestingly, pharmacologic doses of CCK potentiate insulin secretion and decrease postprandial glycemia in type 2 diabetic subjects.⁸⁹ Similarly to CCK, secretin stimulates insulin secretion only at plasma levels that are clearly pharmacologic and so is not likely to play a physiologic role as an incretin. Gastrin also stimulates insulin secretion at levels significantly above what are normally measured following meals. However, in several disease states hypergastrinemia is common, so it is possible that this peptide may affect insulin secretion in specific patients.² Somatostatin-28 (S-28) is released from the upper GI tract in response to protein- and fat-containing meals. Plasma levels peak in the later phases of nutrient absorption, and in physiologic amounts S-28 inhibits insulin release. This peptide has therefore been proposed as a decretin that slows β -cell secretion as carbohydrate delivered from the gut wanes.⁸⁸

There are a number of neural peptides produced in the GI tract that are also contained in neurons innervating the pancreatic islets.⁹⁰ While not true incretins, it is likely that signaling via these autonomic transmitters plays a role in insulin secretion in response to meals. Pituitary adenylate cyclase activating polypeptide (PACAP), vasoactive intestinal polypeptide (VIP), and gastrin-releasing peptide (GRP) are contained in parasympathetic neurons and likely play a role in neurally mediated insulin secretion. As an example, mice with targeted gene deletion of the PAC1 receptor, an important target for PACAP, have impaired insulin secretion and increased plasma glycemia in response to gastric glucose loads.⁹¹ This finding suggests that signaling through neural pathways that release PACAP is activated by glucose in the GI tract and promotes insulin release, and is consistent with a large body of literature implicating the autonomic nervous system in physiologic insulin secretion. It is clear that in humans and other mammals neurally mediated insulin secretion occurs soon after food consumption, before sufficient nutrients have been absorbed to change circulating levels of glucose and other substrates. Although it comprises a relatively small amount of the total postprandial insulin released, this early, or cephalic-phase, insulin secretion has been shown to be important for normal glucose tolerance.⁹⁰ The contribution of neural sig-

nals to insulin secretion during the absorptive phase of meals is not as clearly established, but it is plausible that parasympathetic cholinergic or peptidergic inputs synergize with substrates and incretins to regulate the β cell.

SUMMARY

Insulin secretion during nutrient ingestion and absorption is finely controlled by the interactions of hyperglycemia, neural signals, and incretins. The incretin effect is essential for normal glucose tolerance, and it appears that the contributions of both GIP and GLP-1 are important in this regard. It is not surprising that GIP and GLP-1 have additional activity beyond the stimulation of insulin release, and it appears that these extra-incretin actions tend to complement the incretin effect by promoting nutrient assimilation and/or glucose homeostasis. Major questions remain as to the role of the incretins in normal physiology. Central among these are the specific roles, as well as the interactions, of GIP and GLP-1, the nature of nutrient-K/L-cell coupling leading to incretin release, and the mechanisms and physiologic significance of the extra-islet effects of incretins. In addition, there are important areas for future research relating the incretins and diabetes. For example, the cause of the impaired incretin effect in type 2 diabetes and the ultimate contribution of this defect on postprandial glycemia has not yet been determined, but is likely to provide both pathogenetic and therapeutic insights. Understanding the apparent loss of β -cell responsiveness to GIP, but not GLP-1, in type 2 diabetes may explain the decreased incretin effect in these patients. In addition, this line of inquiry has the potential to uncover important intra- β -cell signaling pathways and sites of dysfunction. Finally, there are numerous exciting possibilities currently under investigation for harnessing the incretin pathways to improve insulin secretion and glucose tolerance. Thus the long history of research devoted to enteric hormones and their regulation of insulin secretion may soon result in tangible benefits for patients with diabetes.

Glucagon

John M. Amatruda

James N. Livingston

INTRODUCTION

Glucagon, through its effects on the liver, is an important regulator of glucose and lipid metabolism in health and disease. Murlin and Kimball discovered glucagon in 1923, and the peptide was first purified and its biological actions studied in the 1940s and 1950s. Proof of its hormonal status was not available until the development of a radioimmunoassay for glucagon in 1959. In the 1960s and 1970s, the α (alpha) cell was shown to be a vital component of the islets of Langerhans and glucagon was found to play an essential role in the overproduction of glucose and ketones in diabetes. By 1985, the role of glucagon in health and disease was largely understood.

In the 1980s and '90s, most research focused on the molecular and cell biology of glucagon including the preproglucagon gene, its distribution and regulation, the processing of the prohormone, and the cloning and characterization of the glucagon receptor. In addition, newer *in vivo* techniques and animal models have refined our knowledge of the importance of glucagon in glucose homeostasis. This chapter will review the regulation and function of glucagon at the molecular, cellular, and physiological levels.

THE GLUCAGON GENE AND ITS PRODUCTS

Preproglucagon Gene

The preproglucagon gene apparently arose from the duplication of an ancestral gene over 800 million years ago.¹ The gene for preproglucagon is located on the long arm of chromosome 2^{2,3} and has six exons of which four encode the 5'-untranslated region, the signal peptide, the preprohormone, and the 3' untranslated region.⁴ Control of the preproglucagon gene is through six identified promoters, which include G1 through G4, CRE (cyclic AMP response element), and ISE (intestine-specific enhancer) (Fig. 7-1).⁵ The promoter activity depends on the tissue in which the gene is being expressed. For example, the G1 promoter, a ~40 nucleotide element located near the TATA box, is acted on by homeoproteins to direct α -cell expression,⁶⁻¹¹ whereas G2 and G3 promoters are enhancers that are active in islets as well as in other cells.^{12,13} The G3 element may mediate the suppressive insulin response found in studies of glucagon gene expression in islets.¹⁴ The CRE is located near the G3 element and responds to cyclic AMP-mediated events. The presence of this promoter is consistent with the finding in

α cells that elevation of cyclic AMP increases preproglucagon gene expression.¹⁵⁻¹⁷

Less is understood about the control of preproglucagon gene expression in sites other than the α cell. For example, intestinal L cells appear to use the ISE promoter element, although other upstream elements are also required.^{5,18}

TISSUE EXPRESSION OF PREPROGLUCAGON

Preproglucagon can be demonstrated in a variety of cells. The most important sites of production are the α cells in pancreatic islets and L cells in the jejunum, ileum, and to a lesser extent in the duodenum and large bowel. Other locations of preproglucagon expression are specific neurons in the brain (hypothalamus, cerebral cortex, amygdaloid nuclei, and medulla oblongata)¹⁹ and "a cells" in the gastric fundus of the dog.²⁰

There are a number of peptides that can be produced from preproglucagon. The peptides generated depend on posttranslational processing of the preprohormone at dibasic amino acid sites.²¹⁻²⁵ Enzymes called prohormone convertases, which process prohormones, are involved in the cleavage of preproglucagon to glucagon. Two of the convertases, PC2 and PC1/3, are found in high concentrations in islet cells. PC2 is thought to convert preproglucagon to glucagon in α cells,²⁶ whereas PC1/3 generates glucagon-like peptides (GLPs) in the intestine.²⁷ Mice with a deficiency of PC2 generated by knockout experiments have fasting hypoglycemia consistent with a deficiency in circulating glucagon.²⁸

Figure 7-2 shows the different peptides generated from preproglucagon by α cells in pancreatic islets or by L cells in the intestine. Depending on the tissue, a number of peptides have been identified from preproglucagon processing.²⁹ These peptides include GRPP (glucagon-related pancreatic peptide), glucagon, IP-1 (intervening peptide-1), GLP-1, IP-2 (intervening peptide-2), and GLP-2. In the α cell, the glucin fragment, which contains sequences for GRPP, glucagon, and IP-1, is first processed to oxyntomodulin, a fragment that contains glucagon and IP-1. This latter peptide is further processed to form glucagon. Small amounts of oxyntomodulin representing about 10–15% of the glucagon content can be found in α cells. A large C-terminal fragment of preproglucagon is also present and has the sequences of GLP-1 and GLP-2. However, the α cell cannot efficiently generate GLP-1 or GLP-2 from this fragment.

FIGURE 7-1. DNA control elements for the rat glucagon gene. ISE, intestine-specific enhancer; CBS, CAP-binding site; CRE, cyclic AMP response element; CES, C/EBP enhancer site; G1–G4, major α cell/islet enhancers; TATA, TATA box. (Modified from Kieffer et al.²⁹)

In L cells, the processing of preproglucagon generates GLP-1, GLP-2, and glicentin, which in this cell type is further processed into oxyntomodulin and GRPP.²⁹ Unlike the α cell, the L cell cannot generate glucagon from oxyntomodulin. Overall, these findings with α cells and L cells point to a remarkably cell-specific processing of preproglucagon to generate an array of gene products fashioned for the needs of a particular tissue.

The processing of preproglucagon in the brain generally corresponds to the processing in the intestine.^{30–35} Interestingly, however, glucagon can be found in fetal brain, but this processing ability disappears as the brain matures.

A miniglucagon has been reported in plasma that represents the 19–29 amino acid fragment of glucagon.³⁶ The short half-life of the fragment and the failure to find significant amounts in the cir-

culatation suggests that miniglucagon is produced from glucagon at the surface of the hepatocyte, where the fragment is purported to act.³⁷ Studies of the effects of miniglucagon on liver indicate that the fragment has different actions than glucagon, although the importance of these effects is not clear, nor has a possible physiological role for this fragment been established.³⁷

GLUCAGON SYNTHESIS AND SECRETION

The rate-limiting step in the synthesis of glucagon by α cells is the production of preproglucagon. The elevation of cyclic AMP increases preproglucagon gene expression with the consequent increase in preprohormone production. This effect of cyclic AMP

FIGURE 7-2. Processing of the proglucagon to peptides in intestinal L cells and pancreatic α cells. GLP, glucagon-like peptide; GRPP, glicentin-related pancreatic peptide; IP, intervening peptide. (Modified from Kieffer et al.²⁹)

may demonstrate synergy with elevations in Ca^{++} to increase the production rate to levels greater than either alone.^{38,39} Membrane depolarization in which calcium/calmodulin-dependent kinase II participates is also part of this process.

In contrast to agents that increase glucagon synthesis, insulin is reported to inhibit preproglucagon gene expression in α cells.⁴⁰ This inhibitory effect is thought to be mediated by an insulin response element in the preproglucagon gene that corresponds to the previously identified enhancer-like element, G3.⁴¹

Expression of preproglucagon in L cells has been monitored by the synthesis and secretion of GLP-1.²⁹ Intestinal cell cultures have shown that cyclic AMP-mediated responses stimulate GLP-1 synthesis and release.^{18,42-44} The release of GLP-1 from L cells involves a rapid response to hormonal and neural signals and a slower response to direct contact with nutrients.²⁹

The secretion of glucagon from α cells is under a complex control system that responds acutely to nutritional and hormonal signals. This acute response is geared to immediate changes in fuel homeostasis.⁴⁵ Because of the complexities in this control system and the likelihood that multiple, parallel changes will occur in a number of regulatory systems in response to metabolic alterations, it is difficult to distinguish direct effects on glucagon secretion from indirect effects. For example, a stimulus that causes insulin release may also be associated with a drop in plasma glucagon. In this case, it is difficult to know if the effect is from a direct action on the α cell or an indirect effect from β -cell stimulation and a consequent increase in insulin secretion, which in itself will reduce glucagon secretion.

The signals to the α cell that regulate glucagon secretion can be divided into neural signals from the nerve endings that surround the pancreatic islet; signals from circulating hormones, especially those from the gut or from other cells in the islets; or signals from fuels, particularly glucose and amino acids. Figure 7-3 illustrates the role of the central nervous system in the regulation of glucagon

secretion in response to hypoglycemia. The neural signals are delivered by adrenergic, cholinergic, peptidergic, and purinergic nerves, and link areas in the hypothalamus to the islets through the autonomic nervous system. Thus stimulation of the ventromedial nucleus in the hypothalamus produces glucagon release while inhibiting insulin release, the latter of which further enhances glucagon secretion.⁴⁶ Likewise, stimulation of the lateral hypothalamus also increases glucagon release.⁴⁷

The release of norepinephrine from sympathetic nerve ending in pancreatic islets activates α_2 - and β_2 -adrenoreceptors on α cell and increases glucagon secretion.^{48,49} Parasympathetic innervation of the islet increases glucagon secretion by the release of acetylcholine and the consequent activation of M_1 and M_3 muscarinic receptors on α cells.^{48,50}

Peptidergic stimulation of α cells involves a growing list of neuropeptides. Glucagon secretion is stimulated by a pancreatic sympathetic neuropeptide like galanin⁵¹ or a parasympathetic neuropeptide like vasoactive intestinal peptide (VIP).⁵² More recently PACAP-27 and PACAP-38 (pituitary adenylate cyclase activating polypeptide), two forms of a neuropeptide related to VIP, were found in human pancreas and shown to cause glucagon secretion.⁵

Gastrointestinal neuropeptides that have activity on α cell include gastrin and cholecystokinin (CCK).⁵⁴ Both peptides apparently act on the CCK-B/G receptor in α cells to stimulate glucagon release. α -Cell function may be altered by serotonin and prostaglandins⁵⁵ as well as GLP-1, which inhibits glucagon secretion *in vivo*.^{56,57} However this effect may be secondary to the potent stimulatory effects GLP-1 has on insulin secretion,⁵⁸⁻⁶⁰ since *in vitro* experiments on isolated islets show a stimulation of glucagon secretion.^{16,17}

Besides neuropeptides from the gut, somatostatin, a peptide produced in the brain, in the GI tract, and in pancreatic islets, is a potent inhibitor of glucagon secretion.⁶¹ The binding of somato-

FIGURE 7-3. Control of glucagon secretion by hypoglycemia. Low plasma glucose has direct and indirect effects on glucagon secretion by the α cell. The indirect effects are through the autonomic system that acts both on the α cell and β cell. A direct effect of low plasma glucose on the α cell is illustrated. The importance of a reduction in insulin secretion for enhanced glucagon secretion is shown.

FIGURE 7-4. Diagram of islet microcirculation in large (left) and small (right) islets. β Cells are shown in the core of the islets and the α cells and other non- β cells are in the periphery. (Modified from Unger et al.⁶⁸)

statin to the somatostatin receptor SSTR2 is responsible for this effect.⁶² Since δ (delta) cells in the islets secrete somatostatin, the somatostatin effect on glucagon secretion has generally been considered part of the islet's paracrine system.

Argument against a paracrine effect is that the amount of somatostatin in the venous effluent is much greater than the amount needed to maximally inhibit glucagon release.⁶³ Thus, in order for the α cell to function properly, it must be shielded from the majority of somatostatin produced by the islet δ cells.

Insulin is a major regulator of glucagon secretion. Evidence for this regulation has been gathered from perfusion of rat islets with an insulin antibody to neutralize the insulin effects. Antibody perfusion results in a rapid increase in glucagon secretion.⁶⁴ The islet arrangement of the α and β cells and islet microcirculation play a role in this regulation (Fig. 7-4).^{64,65} The β cells are located within the interior of the islet, whereas α cells and other non- β cells are located on the periphery. In the rat the afferent blood vessels enter the islet and pass through to the cortex where they branch to perfuse β cells. The effect of this arrangement is that α cells are exposed to potentially high local concentrations of insulin released by β cells. The effect of insulin on glucagon secretion is possibly one of the most important controls imposed on the α cell. Abnormalities in this control may contribute to the pathophysiology of diabetes by, for example, the increase in glucagon secretion that has been reported in cases where insulin secretion is impaired.^{66,67}

Secretin and IGF-1 (insulin-like growth factor-1) are other hormones associated with a negative effect on glucagon secretion,^{68,69} whereas hormones associated with an increase in glucagon secretion include cortisol, oxytocin, vasopressin, growth hormone, and β -endorphin.^{70,71} The effects of various agents on glucagon secretion are summarized in Table 7-1.

One of the most powerful regulators of glucagon secretion is the plasma level of glucose. A fall in plasma glucose below euglycemia results in a rise in glucagon to protect against hypo-

glycemia.^{72,73} Much of this effect is believed to be secondary to the decrease in insulin that accompanies the fall in glucose and to autonomic changes associated with hypoglycemia.⁴⁸

Amino acids also influence the secretion of glucagon, an effect that is observed in human subjects and in studies of perfused pancreas.⁷⁴ Except for branched-chain amino acids, glucagon secretion is stimulated by essentially all amino acids to varying degrees.⁷⁵ Arginine is a potent stimulator that has been used to test α -cell function. However, less is known about the role of amino acids in glucagon release than the effects of other secretagogues. Because relatively high amino acid concentrations are needed to produce an effect on glucagon secretion, amino acids may not be important physiologic regulators of α -cell secretion.⁶⁸ There is some evidence, however, that preventing the decrease in plasma

amino acids during insulin-induced hypoglycemia enhances the glucagon response.⁷⁶

Free fatty acids (FFA) are another fuel that can influence glucagon secretion. At high concentrations, FFA inhibits glucagon release while stimulating insulin secretion.⁷⁷ Further studies have shown that relatively small changes in FFA in the physiological range can influence the plasma level of glucagon.⁷⁸ However, it is generally believed that the role of glucose predominates over the role of FFA in the regulation of glucagon secretion.⁷⁹

THE GLUCAGON RECEPTOR AND GLUCAGON SIGNALING

The action of glucagon begins with the binding of the hormone to a cell surface receptor. Following its cloning and sequencing, the receptor was shown to be a G-protein-coupled receptor in the family of receptors that includes GLP-1, gastrointestinal peptide (GIP), secretin, PACAP, growth hormone releasing factor (GRF), calcitonin, parathyroid hormone (PTH), and VIP.²⁹ The amino acid sequence identity of the glucagon receptor to the other receptor members varies between 27% and 49%.

The gene for the receptor is located on chromosome 17.⁸⁰ There is apparently only one gene that encodes the receptor and differentially spliced variants have not been identified.⁸¹ Based on mRNA profiling of rat tissues, the glucagon receptor gene is expressed in liver, kidney, heart, adipose tissue, duodenum, stomach, and brain.⁸² Of these, the liver is recognized as the major site of expression. Functional glucagon receptors have been identified in adipose tissue, kidney, pancreatic islets, brain, heart, and intestinal tract.⁸³

The cloned human glucagon receptor contains 477 amino acids. The third intracellular loop of the receptor that associates with G proteins is relatively short. The extracellular portion of the receptor that binds glucagon has been studied by making chimeric receptors

between sequences of glucagon and GLP-1 receptors.⁸⁴ The studies show that a portion of the amino terminal extracellular domain and the first and third extracellular loops are required for glucagon binding, whereas the third, fourth, and sixth transmembrane segments contribute to the specificity of the binding reaction for glucagon. From these findings it appears that most of the extracellular portion of the glucagon receptor participates in binding glucagon. Although the cell surface portions of the receptor are the main binding determinants, glucagon binding can be inhibited by small molecules that act at nonsurface sites on the receptor to perturb its structure.⁸⁵ For example, small compounds that insert into the transmembrane site, Leu 388, block glucagon binding and inhibit glucagon action. These compounds have potential to treat type 2 diabetic subjects by reducing the relative overstimulation of glucagon that is a factor in the excessive production of glucose found in this disease.

The molecular events involved in glucagon action are shown in Fig. 7-5. Following binding of glucagon, the glucagon receptor interacts with a G-coupled protein to generate an increase in cyclic AMP through the adenylate cyclase system.^{86,87} The finding that GTP was required during glucagon stimulation of the cyclase system led to the important discovery that GTP-coupled proteins are needed to mediate the actions of seven transmembrane receptors.⁸⁸ The GTP-coupled protein that functionally links the glucagon receptor to adenylate cyclase is Gs, a trimeric protein in its unstimulated state. The interaction of the glucagon receptor complex with Gs provokes the exchange of GDP in the nucleotide-binding site for GTP. The α -subunit of the Gs trimer is then liberated to interact with and activate adenylate cyclase to produce cyclic AMP from ATP.⁸⁹ Termination of this activation occurs with the slow hydrolysis of GTP to GDP by the GTPase activity inherent in the α -subunit.⁹⁰

A less studied signaling pathway for glucagon action is through an increase in Ca^{++} .⁹¹ It is not clear if the increase in

FIGURE 7-5. Activation of the liver adenylate cyclase system by glucagon (Glu). Binding of glucagon to the glucagon receptor (GR) causes the exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) in the α -subunit of the GTP-binding protein. This freed subunit activates adenylate cyclase (AC) to produce cyclic AMP from adenosine triphosphate (ATP). Cyclic AMP in turn activates protein kinase A (PKA) which phosphorylates enzymes that control glucose metabolism in the glycogenolytic, glycolysis, and gluconeogenesis pathways.

Ca^{++} is secondary to the effects of glucagon on cyclic AMP levels or if it involves another signaling system. This second pathway may be the IP-3 system, which is coupled to $\text{G}\alpha_q$ or G_{11} .⁹² Regardless, the best-documented system for glucagon action is the activation of the adenylate cyclase system and an increase in cyclic AMP levels.

METABOLIC EFFECTS OF GLUCAGON

The action of cyclic AMP starts with its binding to regulatory subunits of inactive protein kinase A (PKA). The binding activates the catalytic subunits by allowing them to dissociate from the regulatory subunits that restrain catalytic activity.⁹³ The freed catalytic subunits migrate to target proteins and phosphorylate serine and threonine residues in specific amino acid motifs. The changes in the phosphorylation state of proteins is a well recognized regulatory process for acutely modifying the activity and function of a large number of different proteins.

Reversal of these effects includes the action of phosphodiesterases that reduce the level of cyclic AMP through hydrolysis to AMP. This is reputedly the mechanism by which insulin inhibits the actions of glucagon in the liver cell (i.e., by activating a phosphodiesterase to lower cyclic AMP levels).⁹⁴ A second level of reversal is the conversion of the phosphorylated protein to its non-phosphorylated form by the actions of protein phosphatases.

GLUCAGON ACTION ON LIVER ENZYMES

Glucagon is a major contributor to the regulation of liver enzymes involved in glucose metabolism. This regulation is through elevations in cyclic AMP levels, although some effects of the hormone may be mediated through the Ca^{++} , IP-3 system. Both systems provide similar overall effects on liver glucose metabolism.⁹⁵

Among the metabolic systems controlled by cyclic AMP are glycogenolysis, glycolysis, and gluconeogenesis (Fig. 7-6). As illustrated, the overall consequence of unimpeded glucagon stimulation is an increase in hepatic glucose production, resulting from elevated glycogen breakdown (glycogenolysis), an increase in the synthesis

of glucose from gluconeogenic precursors (gluconeogenesis), and a decrease in the rate of glucose catabolism (glycolysis). Because three different pathways are involved, the changes induced by glucagon in each must be exquisitely coordinated. These changes can be divided into short-term and long-term. The short-term changes, which acutely alter the catalytic activities of key enzymes, are mediated by protein phosphorylation or by allosteric regulation. The long-term changes result from the regulation of gene expression for particular enzymes in the glycolytic and gluconeogenic pathways. Both types of regulation are carried out by the cyclic AMP system and both play important roles in glucagon regulation of glucose metabolism.

Glycogenolysis

Glucagon's effect on glycogenolysis is geared to provide a rapid increase in hepatic glucose production that counteracts dropping plasma glucose levels. The action of glucagon begins with an elevation in cyclic AMP, which activates protein kinase A, to set in motion the cascade shown in Fig. 7-7. The first step in glycogenolysis is the phosphorylation and consequent activation of phosphorylase *b* kinase. Active phosphorylase *b* kinase then catalyzes the phosphorylation of inactive phosphorylase *b* to generate its active form, phosphorylase *a*. This phosphorylation is on serine-14, which provides enough conformational change to activate the enzyme.⁹⁶ Phosphorylase *a* cleaves glycogen at its nonreducing end to generate glucose-1-phosphate, which is available for energy production or for glucose formation. Since the activity of phosphorylase *a* is the rate-limiting step in liver glycogenolysis, activation of phosphorylase regulates the amount of glucose generated from glycogen. A specific phosphatase converts the active *a* form back to the inactive phosphorylase *b* form. Insulin provides an important inhibitory action on this system by reducing the level of cyclic AMP through an increase in phosphodiesterase activity.⁹⁴

Glycolysis and Gluconeogenesis

These two pathways are mirror images of each other, but with important distinctions. Since both pathways have interlocking control systems, they will be discussed together.

In order to increase hepatic glucose production, glucagon must inhibit glycolysis and increase gluconeogenesis. A key regulatory step acted on by glucagon that impacts both pathways is the modulation of the two separate catalytic activities mediated by the bifunctional enzyme 6-phosphofructose-2-kinase/fructose-2,6 bisphosphatase (Fig. 7-8). The overall consequence of bifunctional enzyme activity is to regulate the level of fructose-2,6 bisphosphate. This phosphorylated sugar has major effects on both glycolysis and gluconeogenesis through its acute allosteric regulation of two enzymes, 6-phosphofructose-1 kinase (glycolysis) and fructose-1,6 bisphosphatase (gluconeogenesis). The overall effect is that a high level of fructose-2,6 bisphosphate stimulates glycolysis and a low level allows gluconeogenesis to proceed.

As Fig. 7-8 shows, the bifunctional enzyme catalyzes two opposing reactions, one of which (the kinase activity) forms fructose-2,6 bisphosphate from fructose-6 phosphate, and the second (the phosphatase activity) hydrolyzes the bisphosphate sugar back to fructose-6 phosphate. The net effect is determined by cyclic AMP-dependent phosphorylation of the enzyme.^{97,98} When the bifunctional enzyme is phosphorylated, its phosphatase activity predominates, which reduces the level of fructose-2,6 bisphosphate through its hydrolysis to fructose-6 phosphate. In contrast, in the

Glucagon Stimulation

FIGURE 7-6. Effects of glucagon on the metabolic pathways that produce an increase in hepatic glucose production.

FIGURE 7-7. Steps in the cyclic AMP-mediated increase in glycogenolysis.

FIGURE 7-8. Changes in glycolysis and gluconeogenesis induced by cyclic AMP. Cyclic AMP acting on the bi-functional enzyme 6-phosphofructose-2-kinase (**F-6 kinase**)/fructose-2,6 biphosphatase (**F-2,6 Pase**) regulates the level of fructose-2,6 biphosphate. The level of this phosphorylated sugar regulates the rates of glycolysis and gluconeogenesis as shown. Glucagon produces an increase in cyclic AMP and insulin produces a decrease in cyclic AMP.

presence of low cyclic AMP, the nonphosphorylated form of the enzyme dominates, and thus generates fructose-2,6 bisphosphate from fructose-6 phosphate.

The key rate-controlling enzyme in glycolysis that is regulated by fructose-2,6 bisphosphate is 6-phosphofructose-1 kinase. Thus a decrease in fructose-2,6 bisphosphate from high cyclic AMP levels results in a decrease in 6-phosphofructose-1 kinase activity and a corresponding decrease in glycolysis. When cyclic AMP levels are low, an increase in fructose-2,6 bisphosphate occurs with a consequent allosteric-mediated increase in 6-phosphofructose-1 kinase activity that promotes glycolysis.

Gluconeogenesis is controlled by the enzymatic activity of fructose-1,6 bisphosphatase. In turn its activity is controlled by the level of fructose-2,6 bisphosphate, but in an opposite manner to glycolysis. Thus high levels of fructose-2,6 bisphosphate inhibit this enzyme and reduce the rate of gluconeogenesis, whereas low levels allow the enzyme to act and thereby increase glucose production. Various physiologic states regulate glucose metabolism in liver through changes in fructose-2,6 bisphosphate. For example, in the fed state (low glucagon and high insulin), the levels of fructose-2,6 bisphosphate are increased, which increases glycolysis and inhibits gluconeogenesis. In contrast, a decrease in fructose-2,6 bisphosphate occurs in the starved state (high glucagon and low insulin) or in poorly controlled diabetes, both of which result in an increase in gluconeogenesis and a decrease in glycolysis.

Other processes also impact on the activities of these pathways. For example, gluconeogenesis is increased by an elevation in the activity of pyruvate carboxylase that occurs during glucagon stimulation. This increase in activity is not mediated through changes in cyclic AMP or by other phosphorylation mechanisms. Glucagon may increase the activity at this step by accelerating pyruvate entry into mitochondria or through mechanisms that involve Ca^{++} or other changes in mitochondrial systems.⁹⁹

Another regulatory point is pyruvate dehydrogenase (PDH), an enzyme complex that generates acetyl CoA in the mitochondria from pyruvate. The importance of this enzyme lies in its competition for pyruvate with pyruvate carboxylase. When PDH activity predominates in this competition, gluconeogenesis is reduced. How glucagon regulates this system is unclear, but the hormone may decrease the activity of the Ca^{++} -sensitive PDH phosphatase,¹⁰⁰ which in turn will reduce PDH activity by trapping the enzyme in its phosphorylated form.

A cytosolic enzyme, pyruvate kinase (L form), also influences the flow of carbon from glucose-6-phosphate to pyruvate. By contributing to the availability of pyruvate, this enzyme helps determine whether glucose is produced, or simply used as fuel during glycolysis. It is clear that the increase in cyclic AMP generated by glucagon stimulation causes an inhibitory phosphorylation of pyruvate kinase and reduces glycolysis.⁹⁹ This reduction allows phosphoenolpyruvate to be diverted to the gluconeogenic pathway.

Long-Term Regulation

The acute changes in enzyme activities are supplemented by longer-term changes in the levels of five important enzymes. However, like the acute changes, the long-term changes from glucagon stimulation are mediated by changes in cyclic AMP levels.⁹⁵ Depending on the pathway involved, the expression of the genes is either increased or decreased by elevated cyclic AMP. Three of the enzymes are in the glycolytic pathway and include glucokinase, 6-

phosphofructose-1 kinase and pyruvate kinase. With glucagon elevation, the levels of all three enzymes are reduced, which provides an important means of sustaining the reduction in the glycolytic response.

Two enzymes in the gluconeogenic pathway, phosphoenolpyruvate carboxykinase and fructose-1,6 bisphosphatase, are elevated through a cyclic AMP-mediated increase in the expression of their respective genes. This is an especially important mechanism to increase the activity of phosphoenolpyruvate carboxykinase, since the activity of this key enzyme is not regulated acutely by phosphorylation or allosteric mechanisms.

In summary, the regulation of hepatic glucose metabolism by glucagon is complex because of the need to orchestrate the activities of three different metabolic pathways. This orchestration results in the production of glucose rather than its use to expand the glycogen depot or in the support of fatty acid synthesis. Acutely, hepatic glucose production is derived from the breakdown of glycogen, which begins to wane after 1–2 hours.¹⁰¹ With more chronic stimulation, hepatic glucose production is sustained by gluconeogenesis, which becomes the major source of glucose after an overnight fast. Acute and chronic regulatory mechanisms are used to provide these changes in glycolysis and gluconeogenesis. Phosphorylation of key enzymes and allosteric controls are imposed to achieve acute regulation while chronic regulation is achieved by changes in the expression of genes that code for key enzymes.

GLUCAGON IN GLUCOREGULATION AND KETOGENESIS

To further understand glucagon's role in glucose regulation, it is necessary to understand its relationship with insulin. Specifically, insulin antagonizes the effects of glucagon on the liver by inhibiting the cyclic AMP system. An unopposed action of insulin on the liver results in a decrease in glycogenolysis, an increase in glycolysis with increases in glycogen and glucose-supported fatty acid synthesis, and a decrease in gluconeogenesis. Because of this antagonism, the ratio of glucagon to insulin is important since it establishes the overall net effect. Thus when insulin is high and glucagon low (e.g., after a high carbohydrate meal), hepatic glucose production is low and glycogen and triglyceride production is high.⁹⁵ In contrast, in the postabsorptive state, glucagon predominates over insulin to provide glucose and maintain euglycemia. For example, in the basal (fasting) state, 75% of the hepatic glucose production is dependent on glucagon action.^{102,103}

Abnormalities in this ratio are especially important in diabetes. In type 1 diabetic subjects, low or absent insulin fails to balance the effects of glucagon, which when left unrestrained overstimulates the liver to produce excessive glucose and ketones. In contrast, type 2 diabetic subjects may have significant amounts of insulin, but the presence of insulin resistance contributes to a functional imbalance between the two hormones that supports inappropriate hepatic glucose production.

Lipids

Ketones are an energy source that does not depend on carbohydrate or protein metabolism to supply energy for the central nervous system during starvation.¹⁰⁴ Glucagon acting on the liver promotes ketogenesis by the fall in fructose-2,6 bisphosphate, which in turn

reduces the rate of lipogenesis. This reduction is followed by a reduction in malonyl CoA that inhibits carnitine palmitoyl transferase-I, the enzyme that esterifies fatty acyl CoA to fatty acylcarnitine.¹⁰⁵ This form of the fatty acid enters mitochondria and undergoes oxidation to ketones. These events occur in situations like diabetes or starvation in which insulin levels are very low and glucagon levels are high. An elevation in plasma free fatty acid levels occurs in such states, which provide enough substrate to generate large amounts of ketone bodies that can supply over half of the energy requirements of the brain.

IN VIVO EFFECTS OF GLUCAGON IN ANIMALS AND MAN

Glucose Production

In the postabsorptive state (i.e., 5–14 hours after a meal) plasma glucose levels are stable and a normal human uses approximately 1.8–2.6 mg glucose/kg/min. Approximately 60% of this is used by the brain and the rest by other tissues, including the formed elements of the blood.¹⁰⁶ The liver is the major source of glucose in the postabsorptive state, with the kidneys contributing a minor component.^{107,108}

Because the liver is the major source of glucose in the fasting state, fasting plasma glucose and hepatic glucose output are closely related. As discussed in detail above, glucagon regulates these processes through its regulation of gluconeogenesis and glycogenolysis (Fig. 7-9).^{109–115} Approximately 66% of the basal glucose output of the canine liver is dependent on glucagon.¹¹⁴ In

dogs, increasing plasma glucagon fourfold increases hepatic glucose output approximately fourfold. This effect is primarily due to an increase in glycogenolysis with no effect on gluconeogenesis (Fig. 7-10).¹¹⁵

The converse (i.e., the effect of selective glucagon deficiency with insulin held constant) is to decrease hepatic glucose output by 70%, requiring glucose infusion to prevent hypoglycemia. This acute effect is due to a decrease in glycogenolysis with no effect of gluconeogenesis. The lack of effect on gluconeogenesis in both cases is at least partly due to the constant insulin infusion that limited substrate supply to the liver (Fig. 7-11).¹¹⁵

The dose–response relationship between hepatic glucose output and hepatic sinusoidal glucagon is illustrated in Fig. 7-12.¹¹⁵ This curve shows the sensitivity of hepatic glucose output to small, physiologic changes in glucagon.

Studies in man largely confirm those in dogs. In overnight fasted humans, isolated glucagon suppression with serum glucose maintained at basal levels leads to suppression of hepatic glucose output of 71% in normal control subjects and 58% in patients with type 2 diabetes (Fig. 7-13).¹¹⁶ Under these conditions, even though gluconeogenesis accounts for 70% of hepatic glucose output,¹¹⁷ glycogenolysis accounts for almost all of the increase in hepatic glucose output after an acute, physiologic increase in glucagon.¹¹⁸ The onset of glucagon action is rapid, with the one-half maximum activation and deactivation occurring in approximately 4.0 minutes.¹¹⁹

In the postabsorptive period in man, suppression of glucagon secretion with somatostatin and replacement of insulin leads to a reduction of plasma glucose by ~33% and a reduction in hepatic glucose output of about 50%.¹²⁰ Hypoglycemia is prevented be-

FIGURE 7-9. The relationship between hepatic glucose production and fasting plasma glucose in normal weight diabetic subjects (**open circles**) and in age- and weight-matched control subjects (**closed circles**). (Reproduced with permission from DeFronzo.¹⁰⁹)

FIGURE 7-10. The effect of a selective increase in glucagon on hepatic glucose output, glycogenolysis (GLY), and gluconeogenesis (GNG) in conscious dogs. All dogs received somatostatin and a portal vein infusion of insulin and glucagon. The closed symbols represent the experiments in which portal vein glucagon was increased and insulin held constant. The open symbols represent control experiments in which glucagon and insulin were held constant and glucose was infused to match the increase in plasma glucose seen in the experimental group. cause of an approximately eightfold increase in plasma epinephrine. Similar results are observed with fasting plus somatostatin with insulin replacement.¹²¹

The ability of glucagon to maintain increased glucose production through its glycogenic action only lasts for approximately 2 hours in normal dogs¹²² and humans.¹²³ In man, as in dogs, the large majority of glucose production in this time period is from glycogenolysis. Higher glucagon levels over a longer period increase gluconeogenesis.¹²⁴ Several mechanisms have been postulated for the waning effect of glucagon after 2 hours, including the suppressive effect of the increase in plasma glucose, an increase in plasma insulin levels induced by the hyperglycemia, a depletion of liver glycogen, and intrahepatic regulation. While all may be important, the waning of glucose output is seen in studies in which glucose and insulin are fixed.¹²⁵ In addition, while glycogen is clearly not depleted, the role of a 25–36% decrease in glycogen stores on glycogenolysis is unknown.^{115,118}

In contrast to the waning effect on glycogenolysis, the effect of glucagon on gluconeogenesis persists and increases in importance with time (Fig. 7-14).^{126,127} This may explain the proposed role for hyperglucagonemia in the sustained hyperglycemia of diabetes.¹¹⁶ Another factor may be the pulsatile release of glucagon and insulin. Under conditions of episodic release, the effects of glucagon on hepatic glucose production are sustained^{128–131} and the ketogenic effects of glucagon also persist.^{112,132}

Following a meal when glucose is being absorbed from the intestine, there is little need for the liver to release glucose. It is therefore not surprising that in normal humans glucagon is suppressed in the postprandial state.^{133–135} This is likely due to the effect of hyperglycemia and hyperinsulinemia, both of which are known to suppress glucagon secretion.¹¹⁶ The complete suppression of he-

patic glucose output occurs within 30 minutes of a meal, with a steady increase from 1–4 hours after the meal that mirrors the plasma glucagon:insulin ratio.¹³⁶

Importantly, glucagon is not suppressed by carbohydrate ingestion in patients with diabetes.^{137–139} This lack of suppression of glucagon results in higher postprandial glucose due to higher rates of hepatic glucose release.¹⁴⁰ The hyperglucagonemia of diabetes thus contributes to hyperglycemia in both the fasting and postprandial states.

COORDINATE CONTROL OF GLUCOSE AND LIPID METABOLISM BY GLUCAGON, INSULIN, AND GLUCOSE

Glucose Production

The ratio of insulin to glucagon and the glucose level in the portal circulation all contribute to the control of hepatic glucose output.^{115,137,141} While the effects of insulin on the liver are due to both direct effects on glycogenolysis and gluconeogenesis and indirect effects on glycolysis and gluconeogenesis from the inhibition of peripheral lipolysis,¹¹⁵ the effects of glucagon on the liver are almost exclusively direct. Recently an effect of glucagon on lipolysis in human adipocytes was demonstrated,¹⁴² but the importance of this effect of glucagon *in vivo* is controversial.¹⁴³ In humans, hyperglycemia itself inhibits hepatic glucose output primarily by inhibiting glycogen phosphorylase, while insulin primarily stimulates glycogen synthase and enhances glycogen cycling.¹⁴⁴ With insulin held constant at basal levels and glucose elevated, suppression of glucagon leads to a marked decrease in glycogen turnover,

FIGURE 7-13. The effects of somatostatin with insulin replaced and glucose held constant at the fasting level (selective glucagon deficiency) on hepatic glucose output (HGO) in control subjects (**left panels**) and patients with type 2 diabetes (**right panels**). (Reproduced with permission from Baron et al.¹¹⁶)

a fivefold increase in glycogen synthesis, and a decrease in the contribution of gluconeogenesis to glycogen synthesis.¹⁴⁵ This supports the important antagonist roles of glucagon and insulin.

Ketogenesis

Ketogenesis is also stimulated by glucagon. Ketogenesis depends on the free fatty acids delivered to the liver and the "ketogenic set" of the liver as determined by the glucagon:insulin ratio.¹⁰⁵ A high glucagon:insulin ratio reduces acetyl CoA carboxylase activity and the intracellular concentration of malonyl CoA. This reduces fatty acid synthesis and stimulates ketogenesis by increasing the activity of carnitine acyltransferase. (Fig. 7-15). The enhanced carnitine acyltransferase activity seen in ketotic animals was shown to be from an increase in carnitine acyltransferase I activ-

ity.¹⁴⁶ In patients with type 1 diabetes, somatostatin infusion during insulin withdrawal markedly attenuated the appearance of hyperglycemia and ketoacidosis (Fig. 7-16).¹⁴⁷ Alanine levels rose dramatically in the presence of somatostatin, most likely because gluconeogenesis is inhibited. These data suggest that over the time period of the study, glucagon is necessary for the appearance of severe hyperglycemia and ketoacidosis. Similar studies have been performed following the withdrawal of continuous subcutaneous insulin infusions with and without somatostatin.^{148,149} In dogs, in the absence of glucagon, somatostatin-induced hypoinsulinemia fails to cause hyperglycemia. Dogs given somatostatin plus glucagon to restore glucagon levels to normal become hyperglycemic.¹¹¹ In alloxan diabetic dogs, somatostatin reduces glucose levels by ~200 mg/100 mL in the absence of exogenous insulin.¹¹¹

FIGURE 7-14. The early and late effects of hyperglucagonemia with insulin held constant on overall glucose production and the conversion of lactate and alanine into glucose (gluconeogenic index) in conscious overnight fasted dogs. (Reproduced with permission from Cherrington et al.¹²⁶)

FIGURE 7-15. The biochemical basis for insulin-glucagon interactions on fuel metabolism in the liver. Glucagon increases and insulin decreases cyclic AMP in the liver. This leads to both direct and indirect effects on enzymes that control glycogenolysis and glycogenesis, gluconeogenesis, lipid synthesis, and ketogenesis. Glycogen synthesis and glycogenolysis are controlled directly by cyclic AMP-mediated phosphorylation and dephosphorylation of glycogen synthase and glycogen phosphorylase. In addition, approximately 50% of the carbon incorporated into glycogen comes from new glucose synthesis via gluconeogenesis.¹⁷⁴ The relative flux of carbon into oxidative pathways (i.e., glycolysis vs. glucose production), is determined by the intracellular concentration of fructose-2,6 biphosphate.⁹⁹ Glucagon decreases and insulin increases fructose-2,6 biphosphate. Gluconeogenesis is also regulated by transcriptional regulation of rate-limiting enzymes in gluconeogenesis. Glucagon increases the transcription of phosphoenolpyruvate carboxykinase (PEPCK) and insulin decreases it. Glucagon and insulin also regulate lipolysis and lipid synthesis through cyclic AMP. The level of malonyl CoA formed during lipogenesis in turn inhibits carnitine palmitoyl transferase 1 (CPT-1), which is the rate-limiting enzyme for the transport of fatty acids into mitochondria for oxidation.¹⁴⁶ Thus in the presence of insulin, lipid synthesis is enhanced and lipid oxidation is inhibited. (with permission from Unger RH, Foster DW: *DIABETES MELLITUS* In: Wilson JD, Foster DW, Kronenberg HM, Larsen PR. *Williams Textbook of Endocrinology*, 6th ed. Saunders:1998;1004.)

FIGURE 7-16. The effect of somatostatin on plasma β -hydroxybutyrate (β -OH Butyrate), glucose, and glucagon levels after acute withdrawal of insulin in 7 patients with type 1 diabetes. (Reproduced with permission from Gerich et al.¹⁴⁷)

GLUCAGON AND DIABETES

Glucagon levels are increased throughout the day in poorly controlled patients with type 1 and type 2 diabetes.^{150–152} The magnitude of increase is the same in obese and nonobese type 2 diabetics (Fig. 7-17).¹⁵¹ Glucagon levels are grossly elevated in patients with ketoacidosis,¹⁵² hyperosmolar coma,¹⁵³ and poorly controlled diabetes.¹⁵⁴ Good control of diabetes with insulin restores plasma glucagon levels to normal.^{155,156} In animals, restoration of euglycemia with phlorhizin normalized the suppression of glucagon by glucose.¹⁵⁷ The hyperglucagonemia of diabetes likely results from both the lack of insulin suppression of glucagon secretion in the islet and the effect of chronic hyperglycemia which, through unknown mechanisms, leads to desensitization of the α cells to glucose suppression of glucagon secretion.¹⁵⁴ Patients with total pancreatectomy have decreased levels of gluconeogenesis and increased plasma gluconeogenic amino acids.¹⁵⁸

Patients with glucagon-producing islet cell tumors or glucagonomas have diabetes (67%) or impaired glucose tolerance (23%), necrolytic migratory erythema and stomatitis (64%), weight loss

(56%), and anemia (44%).^{159–161} Patients often have low levels of gluconeogenic amino acids (26%), which is most likely responsible for the rash.¹⁶² The severity of the diabetes is variable, which may be at least partly due to the differential ability to mount an insulin response to the glucagon-induced increase in hepatic glucose output.¹⁶³

As mentioned above, the importance of glucagon in the hyperglycemia of patients with diabetes is at least partially shown by the suppression of glucagon. This leads to a 58% decrease in hepatic glucose output¹¹⁶ in patients with type 2 diabetes, and normalizes glucose in patients with type 1 diabetes.¹⁶⁴ Failure of glucagon suppression also contributes to postprandial hyperglycemia in patients with type 2 diabetes.¹⁴⁰

Glucagon Deficiency

Mice with the glucagon receptor gene removed by homologous recombination have glucose levels in the fed and fasted state that are reduced by approximately 20 mg/dL below control animals [unpublished observations]. These knockout animals also have normal liver glycogen levels, elevated levels of gluconeogenic amino acids

FIGURE 7-17. Mean plasma glucagon concentrations in obese individuals with normal glucose tolerance (open circles) and obese individuals with type 2 diabetes (closed circles). Meals were consumed at 0800 hours and at noon. (Reproduced with permission from Reaven et al.¹⁵¹)

and cholesterol, very high plasma glucagon levels, and normal insulin levels, body weight, fertility, life span and gross pathology. These findings argue that glucagon action is not necessary for survival and reproduction. While not specifically measured, it is likely that severe hypoglycemia is prevented by other counterregulatory hormones. Previous reports of severe hypoglycemia due to glucagon deficiency are likely due to other confounding factors.

A glucagon receptor antagonist given to humans has been shown to decrease the glucose response to a glucagon infusion. Six-

teen normal volunteers were infused with somatostatin and replacement insulin in the absence or presence of hyperglucagonemia. Glucose production increased twofold in the presence of glucagon and this effect was completely blocked by the glucagon antagonist.¹⁶⁵ While it is possible that glucagon receptor antagonists may prove useful in the treatment of type 2 diabetes, additional studies in humans will be necessary to substantiate this utility.

Hypoglycemia

Glucagon plays a primary role in the prevention and correction of hypoglycemia along with epinephrine, growth hormone, cortisol, and in normal individuals, the suppression of insulin (Fig. 7-18). The primacy of glucagon in the prevention of hypoglycemia has been shown during a fast and during exercise in humans.¹⁶⁶⁻¹⁶⁹ In addition, glucagon deficiency leads to a 30% reduction in the nadir plasma glucose concentration following a 75-gram oral glucose tolerance test.¹⁷⁰ Adrenergic blockade and epinephrine deficiency had no effect. Combined glucagon and epinephrine deficiency led to hypoglycemia, with nadir glucose values ~30% lower than glucagon deficiency alone.

Studies of glucose counterregulation from insulin-induced hypoglycemia indicate that glucagon deficiency alone reduces the recovery from hypoglycemia by approximately 40%, while isolated growth hormone or epinephrine deficiency or α - and β -adrenergic blockade have little effect. In the absence of glucagon, however, epinephrine deficiency leads to profound impairment of recovery from hypoglycemia.¹⁷¹ In normal volunteers¹⁷² and in type 1 diabetic patients, the glucagon response to hypoglycemia is suppressed by high concentrations of insulin within the physiologic range.¹⁷³ Thus, at the site of the liver, increases in plasma glucagon along with decreases in plasma insulin are the primary mechanisms for maintenance of normal plasma glucose. In the absence of glucagon or in the presence of nonsuppressed insulin (i.e., insulin-induced hypoglycemia), catecholamines become primary.

FIGURE 7-18. Idealized plasma glucose curves during insulin-induced hypoglycemia in normal subjects during control studies (solid lines) and as modified (dashed lines) by: (A) somatostatin infusion; (B) somatostatin plus growth hormone infusion; (C) somatostatin plus glucagon infusion; (D) phentolamine plus propranolol infusion or studies in patients with bilateral adrenalectomy; (E) somatostatin plus phentolamine and propranolol infusion; and (F) somatostatin infusion in bilaterally adrenalectomized patients.

In summary, the secretion of glucagon and insulin are coordinately regulated and their metabolic effects provide a coordinate regulation of hepatic glucose, amino acid, and lipid metabolism. While insulin's effects are on both the liver and the periphery, glucagon's metabolic effects are exclusively on the liver. These effects occur through cyclic AMP-mediated events to enhance glycogenolysis, gluconeogenesis, and ketogenesis. The importance of glucagon in the regulation of fasting and postprandial glucose as well as ketogenesis in normal and diabetic humans is well documented. Future efforts will focus on the role of inhibiting glucagon secretion or glucagon action in the treatment of patients with both type 2 and type 1 diabetes.

Role of the CNS in Glucose Regulation

Mark L. Evans

INTRODUCTION

The human brain is an extremely active metabolic organ. Despite making up only 2% of adult body weight, it receives about 800 mL/min (15%) of the cardiac output and consumes approximately 50 mL/min of oxygen, representing 20% of the body's resting glucose consumption. Although early measurements may have underestimated the glycogen content of brain tissue, the energy stored as glycogen is only sufficient to fuel the brain for a few minutes if it were the sole energy supply.¹ The central nervous system (CNS) is thus largely dependent on circulating glucose as its predominant source of energy, with cognitive performance becoming impaired during moderate hypoglycemia. If the blood glucose falls low enough, coma or even permanent brain injury or death may eventually occur.²

In contrast to most tissues of the body, brain parenchyma is separated from the bloodstream by the endothelial blood-brain barrier. In order to reach and fuel neurons, glucose from the bloodstream must traverse luminal and abluminal membranes of endothelial cells and possibly also through astrocyte foot processes to enter the extracellular fluid (ECF) of the brain. Although there is some simple nonsaturable diffusion of glucose across the blood-brain barrier, most transport across these membranes is effected by the facilitative glucose transporter GLUT-1 (Fig. 8-1). GLUT-1 is also referred to as the red blood cell transporter, and in contrast to GLUT-4 is insensitive to the actions of insulin. GLUT-1 exists in both glycosylated (55 kD) and nonglycosylated (45 kD) forms in the CNS in the endothelium and astrocytic compartments, respectively, although the functional significance of these differences is uncertain. Glucose in the brain ECF may then enter into neurons by the facilitative transporter GLUT-3.

Glucose levels in brain are lower than in plasma, suggesting that the blood-brain barrier limits the supply of glucose for the central nervous system, with most estimates of ECF glucose being between 20% and 30% of plasma values. CSF glucose values are higher than in ECF, with typical values being 50–70% of plasma glucose.

Although the main fuel supply for brain tissue is undoubtedly glucose originating from the bloodstream, there is increasing evidence that neurons may be able to metabolize nonglucose fuels. A

number of alternate substrates may support neuronal metabolism in brain slice studies in which the blood-brain barrier is absent. During *in vivo* human studies, lactate and the ketone β -hydroxybutyrate have been demonstrated to support, at least in part, brain metabolism and cognitive functioning during hypoglycemia.^{3–5} For some of these substrates, the physiological relevance of their metabolism by brain tissue is questionable. However, lactate appears to be a genuine brain fuel, with some *in vitro* studies even suggesting that lactate may be preferred over glucose by neurons.⁶ In contrast to glucose, lactate levels in the brain ECF are higher than plasma lactate values (suggesting that lactate is synthesized locally) and brain ECF glucose values.⁷ The significance of glycogen stores in astrocytes is uncertain. One possibility is that astrocytic glycogen stores act as a buffer against a sudden rise in neuronal energy requirements during local brain activation, but with lactate rather than glucose being released. Whatever the exact metabolic pathways involved in fueling neurons, it seems likely that astrocytic and neuronal metabolism are coupled. It is important to emphasize, however, that regardless of the exact pathway(s) involved within the CNS, glucose from the bloodstream is the predominant source of energy to support neuronal metabolism and function.

The main energy-consuming activities of the CNS are biosynthesis and transport—mostly of ions and neurotransmitters. In particular, an important energy-requiring activity is the clearance of neurotransmitters such as glutamate from the ECF. Glutamate is the main excitatory neurotransmitter in the CNS but may produce brain toxicity if extracellular levels are high and/or sustained. A glutamate-glutamine cycle exists so that glutamate released from neurons is rapidly taken up by astrocytes and subsequently converted to glutamine. The uptake of glutamate is driven by the cell membrane sodium-potassium pump (Na^+ , K^+ -ATPase), a process dependent on ATP derived from glucose. The glutamine produced in astrocytes is then transported back into neurons for conversion into glutamate and storage in secretory vesicles for subsequent release.⁸ Thus the glutamate-glutamine cycle requires a sufficient supply of glucose to maintain astrocytic functioning and this appears to be associated with anaerobic glycolysis and release of lactate from glia. During profound hypoglycemia, the lack of energy for these homeostatic mechanisms may result in rises in glutamate and aspartate in brain interstitial fluid. These excitotoxins act on

Blood-Brain Glucose Transport

FIGURE 8-1. Glucose transport from vascular lumen to neurons involves the facilitative glucose transporters GLUT-1 and GLUT-3 in endothelium/glia cells and neurons, respectively. (Reproduced from Borg et al.²⁶)

specific receptors such as the NMDA glutamate receptor to trigger further downstream effects that may eventually result in brain damage by cell apoptosis or necrosis. It is unclear whether the more moderate hypoglycemia seen during the day-to-day management of diabetes causes a similar perturbation of excitatory neurotransmitters. Indeed, it is possible that milder degrees of hypoglycemia are accompanied by an adaptive reduction in neurotransmission that would protect the brain against excessive accumulation of excitotoxins at the expense of impaired function.

The central nervous system has a key regulatory role in glucose homeostasis. In particular, the brain is important in initiating and coordinating protective counterregulatory responses in the face of a falling blood glucose. This role is probably a consequence of the central nervous system's metabolic dependence on glucose so the brain will tend to protect its own fuel supply. In health, blood glucose is normally maintained within a relatively narrow range. A number of rare medical conditions such as insulin-secreting tumors of the pancreas may overcome or suppress these defenses and cause hypoglycemia, but by far the most significant cause of hypoglycemia in clinical practice is the treatment of diabetes with insulin or insulin secretagogues. As described later in this chapter, the risk of hypoglycemia in diabetes may be further increased by defects in the defensive counterregulatory responses triggered by the central nervous system in response to a low glucose concentration (See Chapter 31).

ROLE OF THE CNS IN THE RESPONSE TO HYPOGLYCEMIA

Counterregulatory Defenses Against Hypoglycemia

A hierarchy of defensive counterregulatory neurohumoral responses is triggered by a fall in blood glucose. The cessation of insulin secretion from the healthy pancreas is an important early step in nondiabetic subjects,⁹ and the subsequent release of the hormone glucagon acts in concert with the fall in insulin to increase glucose production by the liver.¹⁰ The precise mechanisms responsible for the activation of glucagon release from pancreatic α cells is

not clear, but they may be dependent on both local pancreatic detection of hypoglycemia and on central brain-dependent control via pancreatic innervation, as well as stimulation of circulating catecholamines.

Increased glucagon and decreased insulin release in response to a falling blood glucose are a potent combination that will tend to rapidly restore normal blood glucose levels in healthy subjects. Other counterregulatory neurohumoral changes also occur during hypoglycemia. In particular, the catecholamines epinephrine and (to a lesser extent) norepinephrine are released from the adrenal medulla under the control of preganglionic sympathetic neurons. In addition to this direct release of norepinephrine from the adrenal medulla, norepinephrine also appears in the bloodstream as a consequence of the increase in autonomic sympathetic outflow to other target tissues, resulting in some spillover from synapses into the circulation. In general, catecholamines, both in the circulation and by direct neural innervation, will act quickly to decrease glucose uptake into peripheral tissues and increase endogenous glucose output (from liver and perhaps also kidney) both directly and indirectly by increasing the supply of gluconeogenic precursors and free fatty acids from muscle and adipose tissue.¹¹

Cortisol also rises during hypoglycemia, probably via a sequence of events involving activation of parvocellular neurons in the hypothalamic paraventricular nucleus, subsequent release of CRH from projections of these neurons in the median eminence, and subsequent ACTH release from corticotroph cells in the anterior pituitary. Growth hormone is released from the anterior pituitary during hypoglycemia, mainly as a result of changes in releasing factors from hypothalamic areas (i.e., GHRH) and/or a fall in inhibitory factors such as somatostatin. Cortisol and growth hormone exert a number of both direct and indirect effects to decrease glucose uptake into peripheral tissues and to promote endogenous glucose production.^{12,13} However, these changes take time to occur, and therefore their actions are important when hypoglycemia is sustained. A number of other neuroendocrine changes also occur during hypoglycemia, such as increased endorphin and vasopressin release, although the significance of these is unclear.

These neurohumoral responses will tend to diminish, prevent, or correct a falling blood glucose by direct metabolic effects to antagonize the effects of insulin. These metabolic defense systems are complemented by the generation of symptoms—both those believed to be associated directly with the neurohumoral responses (such as heart palpitations from increased adrenergic drive and sweating linked to activation of cholinergic sympathetic fibers) and those resulting from brain neuroglycopenia such as behavioral changes. In patients with diabetes who have been suitably educated, these symptoms may warn of impending hypoglycemia and allow appropriate actions to correct blood glucose that depend on cognitive areas of the brain being able to function sufficiently to do what is necessary. Clearly, if blood glucose has fallen too low, these cognitive areas may not function sufficiently to effect rescue of blood glucose and severe hypoglycemia requiring third-party rescue may occur.

One symptom worthy of special mention is hunger, which not only warns of low glucose, but will also provoke eating to aid correction of blood glucose. The exact mechanisms by which hunger is generated during hypoglycemia are unknown, but it is worthy of note that many of the areas of the brain thought to be involved in glucose homeostasis, such as the ventromedial and lateral hypothalamic areas, are also thought to be important in control of appetite and satiety.

Sensing of Hypoglycemia

In order for the above protective responses to occur, the body must first detect hypoglycemia. The exact site or sites at which a low glucose level is detected and which of these sites, if any, is dominant remains controversial. However, considerable evidence suggests that brain areas play a critical role in sensing low blood glucose.

Outside the brain, pancreatic glucose sensing is important in nondiabetic subjects for triggering the cessation of insulin release, and this in turn is probably the dominant influence resulting in increased glucagon release during hypoglycemia. It is noteworthy in this regard that intraislet blood flow occurs to a large extent from the β -cell-rich core out into the periphery, the predominant location of α cells. Glucose-sensing mechanisms are undoubtedly present in the liver and/or portal vein, although the exact role that these areas may play in the generation of counterregulatory defenses against hypoglycemia is unclear. In support of a role for sensors in the hepatic area, adrenomedullary responses to (but not glucose recovery from) hypoglycemia were blunted by hepatic denervation in dogs.¹⁴ Similarly, adrenomedullary responses to a systemic hypoglycemic challenge were blunted when portal vein (and liver) glucose levels were maintained by selective portal glucose infusion,¹⁵ although it is possible that the arterioportal glucose gradient created might have acted as a feeding signal¹⁶ to suppress counterregulatory responses to hypoglycemia,¹⁷ as we will describe more fully later in this chapter.

In contrast, other work has suggested that hepatic/portal glucose sensors play a minimal role in sensing hypoglycemia. Studies in dogs in which the vagal nerve was cooled to reduce hepatic afferent neural transmission, or in human recipients of liver transplants with resulting hepatic denervation, showed no impairment of counterregulatory hormonal responses to hypoglycemia.^{18–21} Furthermore, oral ingestion of glucose augmented rather than suppressed counterregulatory responses to a controlled hypoglycemic challenge in healthy male subjects, suggesting that portal glucose sensors had little role in sensing hypoglycemia.²² In summary, the contribution of hepatic sensors to counterregulatory responses to hypoglycemia remains unclear. Even if liver or portal vein areas have a significant role in detecting hypoglycemia, it seems likely that these sensors act via coordinating CNS areas to trigger distal counterregulatory responses.

Much of the investigation of brain hypoglycemia sensing has employed either local delivery of nonmetabolizable glucose analogues to create local glucopenia (or the converse strategy of maintaining glucose levels within candidate sensing areas) or lesioning studies. Biggers and associates²³ used arterial catheterization of canine carotid and vertebral arteries to create a model in which brain glucose levels could be selectively maintained at euglycemia in the presence of systemic hypoglycemia. When brain glucose levels were maintained euglycemic, counterregulatory responses (catecholamines, cortisol, pancreatic polypeptide, and glucagon) were attenuated, suggesting that the predominant hypoglycemia sensor lay within the cerebral circulation. Subsequent selective infusion of either vertebral or carotid arteries suggested that both circulations contributed to the sensing area(s).²³

The exact areas involved in CNS hypoglycemia sensing remain a source of debate. Studies by Borg and colleagues^{24–26} suggest that the ventromedial hypothalamus (VMH) is an important area. Lesioning of rat VMH reduced counterregulatory responses to a systemic hypoglycemic challenge.²⁴ Subsequent studies used mi-

crodialysis techniques to deliver substrates directly into the hypothalamus, with counterregulatory responses being triggered by local VMH perfusion of the nonmetabolizable glucose analogue 2-deoxyglucose, or attenuated by VMH delivery of glucose during systemic hypoglycemia (Fig. 8-2).^{25,26} As described below, a number of groups have identified and characterized neurons that respond to changes in blood glucose in the ventromedial (and lateral) hypothalamus.

In contrast, a number of studies have suggested that sensing areas around the brain stem may be predominant. Delivery of the antimetabolic glucose analogue 5-thioglycose (5TG) into the fourth ventricle was more effective in eliciting feeding and hyperglycemic responses than lateral ventricle injection. Acute blockade of the cerebral aqueduct abolished responses to injection of 5TG into the lateral ventricles, but injection into the fourth ventricle did not.²⁷ Using direct microinjection of 5TG into the brain parenchyma, a number of brain sites around the fourth ventricle were identified that triggered feeding and/or hyperglycemic responses. In contrast, a number of candidate hypothalamic areas showed no response to local delivery of 5TG.²⁸ Analogous to the hypothalamus, neurons with the ability to increase or decrease activity in response to changes in ambient glucose have also been identified in brain stem areas such as the nucleus tractus solitarius and area postrema.²⁹

Despite the controversy about the relative importance of the different hypoglycemia sensing sites, it seems most likely that a redundancy of hypoglycemia sensors exists. A number of different sensing areas, both within the brain and possibly outside the CNS, are capable of detecting a low glucose and contributing to counterregulatory responses. Counterregulatory responses to systemic hypoglycemia may represent a coordinated response to complementary information from a number of different sensors.

Mechanisms of Brain Hypoglycemia Sensing

Although the exact mechanisms utilized by the CNS to detect low glucose remain to be defined, it seems to be a fall in cerebral metabolism that triggers counterregulatory responses. Studies

FIGURE 8-2. Delivery by microdialysis of D-glucose (but not nonmetabolizable L-glucose) into the ventromedial hypothalamus in rats,² obtunded counterregulatory responses to a systemic hypoglycemic challenge, suggesting that it is a fall in glucose levels in this area of the brain that initiates counterregulatory responses.

Hypoglycemia Sensing in the VMH

described earlier in the chapter examined the effects of infusion of the nonglucose substrates lactate or β -hydroxybutyrate during hypoglycemia. Counterregulatory responses were attenuated when blood glucose was lowered in the presence of elevated levels of either of these substrates, both capable of fueling brain areas. These studies suggest that it is a fall in cerebral metabolism in specialized brain areas that is the signal initiating counterregulatory responses, rather than a fall in glucose *per se*. In keeping with this view, local delivery of lactate into the VMH region was also sufficient to blunt counterregulatory hormone release during hypoglycemia.

Changes in CNS metabolism are probably detected by specialized neurons that have the ability to alter activity as ambient glucose levels change. The activity of most neurons is unaffected by changes in glucose, unless levels fall too low or so high as to cause a generalized metabolic decompensation. However, it has long been recognized that a subset of neurons from certain brain areas is capable of altering activity in response to changes in ambient glucose levels. Oomura and associates³⁰ first described glucose-responsive neurons in the VMH that increased activity in response to a rise in glucose, and another subset of neurons in the lateral hypothalamus that were inhibited by a rise in glucose. Although these neurons were initially referred to as GR (for glucose responsive) and GS (for glucose sensitive), respectively, the acronyms are not consistently used, with GS being used to describe generic glucose-sensing neurons, for example. More recently GR and GS neurons have been described in both hypothalamic and brain stem areas such as the area postrema and the nearby nucleus tractus solitarius.³¹ Silver and Erecinska³² reported that 30% of lateral hypothalamic neurons responded to changes in glucose. A rise in glucose inhibited activity in neurons termed types 1, 2, and 3, depending on the sensitivity to glucose, or increased activity in neurons labeled as type 4. Similarly, 40% of VMH neurons behaved like type 4 neurons, with an increase in activity with a rise in glucose levels.³²

Further work is needed to determine how the metabolic signal of low glucose is transformed into neuronal electrical activity. One intriguing possibility is that some of the mechanisms utilized by glucose-sensing β cells of the pancreas may be used in brain hypoglycemia-sensing areas. For example, in the classic pathway of β -cell glucose sensing, specialized cell surface potassium channels (potassium ATP channels) allow the changes in energy supply as ATP to be converted into alterations in cell membrane polarization. Similar potassium ATP channels as well as glucokinase have been detected in glucose-sensing neurons from both the ventromedial hypothalamus³³ and brain stem glucose-sensing areas.³⁴

Information about changes in blood and brain glucose levels may allow the central nervous system to contribute to a number of different homeostatic functions such as central control of endogenous glucose production, insulin secretion, and appetite/feeding pathways. Sensing of hypoglycemia may thus represent one end of a continuum of nutritional signaling, with sensory information from both GR and GS neurons and perhaps also peripheral glucose sensors being processed to allow a coordinated response to a threatened fuel supply.

Defective CNS Defenses Against Hypoglycemia in Diabetes

As described above, the CNS has a critical role to play in defending against hypoglycemia and thus protecting its own fuel supply. In diabetes, a number of defenses may be altered, both within and outside the CNS, leading to an increased risk of severe hypoglycemia.

Diabetic patients treated with insulin or insulin secretagogues are unable to reduce insulin release into blood in response to a falling blood glucose, resulting in an absolute or relative excess of insulin compared with nondiabetic subjects. In addition, most type 1 diabetic patients develop deficient glucagon responses to hypoglycemia within the first 5 years after diagnosis. Deficient glucagon (and insulin) responses to a falling blood glucose mean that patients are dependent on centrally driven catecholamine responses as the most important neurohumoral response to prevent hypoglycemia.³⁵ Unfortunately, a number of diabetic subjects develop additional defects in catecholamine responses to hypoglycemia. The combination of deficient glucagon and adrenomedullary/catecholaminergic responses and the associated loss of symptomatic awareness of hypoglycemia significantly increases the risk of severe hypoglycemia.^{36,37} (See Chapter 31).

The exact mechanisms involved in abnormal counterregulation in diabetes are unknown. Abnormal glucagon responses that develop in most insulin-deficient patients most likely result from local pancreatic changes, although a central brain adaptation may contribute. The former may be, at least in part, a consequence of the loss of local islet insulin secretion, and its inhibitory effect on α -cell secretion. Normally, insulin secretion and intraislet insulin levels paradoxically fall in response to insulin-induced hypoglycemia, but in the insulin-deficient diabetic pancreas, exogenous insulin results in a rise in islet insulin levels that would be expected to suppress glucagon release. Deficient catecholamine defenses against hypoglycemia are believed to be a consequence of an adaptation occurring in those brain areas that sense low glucose and/or initiate counterregulatory defenses. Thus the mechanisms for these two abnormalities may, at least in part, be different. Important risk factors for abnormal counterregulation are intensified glycemic control, longer duration of diabetes, and a history of hypoglycemia *per se*.

There is considerable evidence that the hypoglycemia that occurs as a consequence of treatment of diabetes may itself result in a downregulation of counterregulatory responses to a subsequent hypoglycemic episode. Healthy volunteers exposed to two episodes of relatively mild hypoglycemia display temporary deficits in counterregulatory responses to hypoglycemia on the following day (Fig. 8-3).³⁸ Subsequent work from a number of groups has confirmed that antecedent hypoglycemia can result in a downregulation of subsequent responses to low blood glucose in both healthy and diabetic subjects. In keeping with this hypothesis, defective counterregulation in type 1 diabetes may be improved, at least in part, by scrupulous avoidance of hypoglycemia.³⁹

The mechanisms by which antecedent hypoglycemia can downregulate counterregulatory responses to a subsequent hypoglycemic episode are uncertain. One possibility is that an adaptation in blood-brain glucose transport occurs in response to antecedent hypoglycemia, allowing the brain to maintain better local glucose levels during hypoglycemia. In keeping with this, a number of animal studies have reported increases in endothelial GLUT-1⁴⁰⁻⁴² and/or the neuronal glucose transporter GLUT-3⁴³ following periods of prolonged hypoglycemia.

In human studies, brain glucose uptake has been assessed either by measuring arteriovenous differences in glucose across the brain or noninvasively by using brain imaging techniques. In keeping with the animal data described above, net global brain glucose uptake measured by the difference between arterial and jugular bulb glucose levels was preserved during hypoglycemia in healthy human volunteers previously subjected to 56 hours of interprandial

Antecedent Hypoglycemia Results in Impaired Counterregulation

Heller + Cryer Diabetes 1991

FIGURE 8-3. Hypoglycemia itself downregulates responses to subsequent hypoglycemia. The figure shows baseline and peak epinephrine responses to a brief hypoglycemic challenge in healthy subjects on two successive days. A period of 2 hours of moderate (3 mmol/L) hypoglycemia (but not euglycemia) on the afternoon of day 1 was sufficient to downregulate epinephrine responses to a subsequent hypoglycemic challenge on day 2. (Reproduced from Heller et al.⁴⁶)

hypoglycemia.⁴⁴ Similarly, a study of type 1 diabetic subjects showed that those with good glycemic control and frequent hypoglycemia were able to preserve brain glucose uptake during hypoglycemia.⁴⁵ In contrast, positron emission tomography (PET) scanning using a 1-¹¹C-glucose tracer technique demonstrated no global increase in glucose uptake after 24 hours of interprandial hypoglycemia in healthy volunteers.⁴⁶

One possibility is that regional changes in glucose metabolism in glucose-sensing areas may not be apparent with these measures of global brain glucose metabolism. Using ¹⁸F-fluorodeoxyglucose (FDG) as a tracer during PET scanning, Cranston and associates⁴⁷ reported that regional FDG brain uptake in an area including the ventromedial hypothalamus behaved differently during hypoglycemia in type 1 diabetic subjects with or without impaired counterregulatory defects. In animal studies regional brain metabolism can be examined by using microdialysis or microinjection techniques. Direct delivery by microdialysis of the glucose analogue 2-deoxyglucose (2DG) into the ventromedial hypothalamus in rats simulates local glucopenia and results in a counterregulatory-type response. In this model, the blood-brain barrier is effectively bypassed and substrate is delivered directly into the brain ECF. In animals previously exposed to chronic hypoglycemia, counterregulatory hormonal responses to 2DG delivery were obtunded, suggesting that at least part of the adaptation occurs downstream of blood-brain barrier glucose transport.⁴⁸

An alternate, although not necessarily competing, hypothesis is that the rise in glucocorticoids that occurs as part of the counterregulatory response may activate a negative feedback loop that downregulates counterregulatory responses to a subsequent hypoglycemic challenge. Davis and colleagues⁴⁹ infused insulin and dextrose for two episodes of 120 minutes during the morning and afternoon in healthy subjects on day 1 and examined responses to a controlled hypoglycemic challenge on the next day (Fig. 8-4). When blood glucose was allowed to fall to 50 mg/dL (2.8 mmol/L) during the day 1 episodes, counterregulatory responses on day 2 were suppressed compared to when blood glucose was maintained

at 90 mg/dL (5 mmol/L) on day 1. When cortisol was infused on day 1 at a dose that mimicked the response seen with day 1 hypoglycemia (together with insulin and dextrose to maintain constant glucose levels), counterregulatory responses on day 2 were partially suppressed. These results suggest the downregulation of counterregulation by antecedent hypoglycemia may be in part mediated by cortisol.⁴⁹ A subsequent study by the same group of researchers examined patients with primary adrenocortical failure who underwent a similar 2-day experiment with two periods of controlled hypoglycemia on day 1 with an infusion of cortisol to mimic basal levels only. Responses to hypoglycemia were similar on both day 1 and day 2, suggesting that the absence of a glucocorticoid response to the low blood glucose on day 1 had prevented downregulation of counterregulation with hypoglycemia, although it should be noted that responses in general were less robust than those of a healthy control group.⁵⁰ However, the finding of downregulation with glucocorticoids is not universal. Shum and associates⁵¹ demonstrated no effects of 4 days of corticosterone treatment on neuroendocrine responses to a subsequent hypoglycemic challenge in healthy rats. In contrast, antecedent hypoglycemia or even just exposure to high insulin levels with blood glucose maintained over the previous 4 days resulted in attenuated neurohumoral responses to hypoglycemia.⁵¹

If glucocorticoids are part of the mechanism by which hypoglycemia impairs counterregulatory responses to subsequent hypoglycemia, what might the teleological explanation be? In general, glucocorticoids display a complex series of interactions with stress responses (for review, see reference 52). Glucocorticoids have a permissive or stimulatory role on some aspects of the stress response. For example, deficient glucocorticoid secretion in Addison's syndrome results in impaired responses to a variety of insults as diverse as cardiovascular disruption, sepsis, and infection. On the other hand, glucocorticoids have also been demonstrated to have a role in limiting stress responses that prevent overstimulation, and in preparing the stress axis for future insults, possibly acting via brain steroid receptors. In clinical hypoglycemia, this may

FIGURE 8-4. Glucocorticoids released during hypoglycemia may modulate the downregulation of counterregulatory responses to a subsequent hypoglycemic challenge. Figure shows epinephrine responses to hypoglycemia on day 2 after one of three antecedent treatments given on day 1 (described in text). (Reproduced from Davis et al.⁴⁹)

Glucocorticoids May Mediate Hypoglycemia-Induced Impairment of Counterregulation

Davis et al JCI 1996

be further complicated by the contribution of other components of the hypophysis-adrenal axis such as brain release of CRH that may also modulate stress responses.

It is possible that a number of different adaptations in the diabetic brain including, but not restricted to, alterations in brain glucose transport and feedback from the hypothalamic-pituitary-adrenal axis contribute to impaired CNS defenses against hypoglycemia. Other putative adaptive mechanisms that have been suggested include alterations in brain metabolic pathways in sensing areas, local blood flow, local substrate fluxes (and in particular changes in brain lactate and/or glycogen metabolism), and changes in neurotransmitter pathways.

ROLE OF THE CNS IN THE RESPONSE TO HYPERGLYCEMIA

DeFronzo and colleagues⁵³ showed decades ago that when glucose was delivered through a peripheral vein in the human, the plasma glucose (221 mg/dL) and insulin levels (101 μ U/mL) rose, but splanchnic glucose uptake was minimal. When in the same subjects glucose was given orally and the glucose infusion rate was reduced to maintain the same arterial glucose level, net splanchnic glucose uptake increased more than fourfold (Fig. 8-5). Although the plasma insulin level was increased modestly in the oral group relative to the IV-only group, it is now known that the insulin increment could not explain the larger increase in net splanchnic glucose uptake. Based on their findings, the investigators suggested that a gut factor may play an important role in signaling the liver to take up and store glucose following feeding. Subsequent work in animal models in other laboratories determined that enhancement of net hepatic glucose uptake (NHGU) was evident with portal glucose infusion, and not just with enteral glucose delivery, dispelling the notion that gut factors could be responsible for the findings.⁵⁴⁻⁵⁶

Studies were therefore carried out to try and understand whether the CNS could play a role in the response to oral/portal glucose delivery. It would now appear that glucose uptake and storage by the liver are regulated by three factors: the plasma insulin/glucagon levels, the plasma glucose level, and a signal generated by entry of glucose into the body via the portal vein. In a series of studies employing the conscious dog, it was shown that with insulin increased to fourfold basal, the rate at which the liver took up glucose correlated linearly with the hepatic glucose load (i.e., the rate at which glucose was delivered to the liver).⁵⁷ Administering a small portion of the glucose infusion into the hepatic portal vein shifted the dose-response curve to the left. Thus when the arterial plasma glucose level ranged between 100 and 200 mg/dL, the "portal" signal was responsible for most of the NHGU.

Significance of the Portal Signal in Disposition of a Glucose Load

When the glucose load to the liver was doubled and the insulin level was varied, there was a curvilinear relationship between the insulin level and NHGU⁵⁸ (Fig. 8-6). Once again, infusion of a small amount of glucose into the hepatic portal vein to activate the portal signal shifted the dose-response curve to the left. In fact, the ability of this signal to augment NHGU was equivalent to the effect of a fourfold rise in plasma insulin. Experiments were then carried out in which the insulin level was increased fourfold and the glucose load to the liver was doubled, but the magnitude of the por-

FIGURE 8-5. Normal human volunteers received an intravenous glucose infusion continuously for 4 hours so that they achieved steady-state glucose (221 mg/dL) and insulin (101 μ U/mL) concentrations (IV group). An additional group (IV + oral) received an intravenous glucose infusion to achieve similar hyperglycemia and hyperinsulinemia to the IV group. After steady-state glucose concentrations were reached, they ingested glucose 1.2 g/kg, and the peripheral glucose infusion rate was adjusted to maintain their plasma glucose at ~220 mg/dL. Net splanchnic glucose uptake was significantly enhanced by oral glucose ingestion, an effect not solely attributable to the relatively small differential in insulin concentrations between groups. (Redrawn from DeFronzo et al.⁵³)

tal vein and peripheral vein glucose infusion rates was varied so as to create a range of arterial-portal (A-P) glucose gradients. There was a curvilinear dose-response relationship between the A-P glucose gradient and the fractional uptake of glucose by the liver (Fig. 8-6),⁵⁹ such that the signal was most effective with a low glucose load and, in fact, saturated at an A-P gradient of about 20 mg/dL, a physiologic gradient observed in the postprandial state.

It was further demonstrated that the portal signal, while augmenting glucose uptake by the liver, decreased muscle glucose uptake.⁶⁰ Thus, instead of regulating whole-body glucose clearance, in this way it tended to control the distribution of glucose between the liver and muscle (Fig. 8-7). The suggestion was also made that the portal signal had a mild incretin effect, thereby raising the plasma insulin level and thus also promoting whole-body glucose clearance.⁶¹⁻⁶³ This is consistent with data demonstrating a relationship between hepatportal glucose sensors and insulin secretion. Hepatic vagotomy attenuated insulin secretion following intraportal or intraperitoneal glucose administration in the rat, but it did not decrease insulin release following peripheral intravenous glucose injection.^{64,65} Moreover, injection of glucose into the portal vein decreased the afferent firing rate in the hepatic branch of

FIGURE 8-6. Net hepatic glucose uptake is enhanced by portal vein versus peripheral glucose infusion over a wide range of insulin concentrations (top panel). With the hepatic glucose load at twofold basal and plasma insulin at fourfold basal, net hepatic fractional extraction of glucose is directly related to the magnitude of the negative arterial-portal vein glucose gradient, an effect that saturates above a gradient of approximately -20 mg/dL (bottom panel). (Top panel: redrawn from Myers et al.⁵⁸ Bottom panel: redrawn from Pagliassotti et al.⁵⁹)

the vagus nerve, but at the same time it increased the firing rate of the vagal pancreatic efferents, an effect ablated by sectioning the hepatic branch of the vagus.⁶⁶

This synchronized pattern of response led to the hypothesis that the portal signal involves the CNS. Certain evidence has now accumulated to support this hypothesis. The speeds of onset and offset of the response of the liver to an alteration in the portal signal are rapid. A maximal response to the portal signal was seen within 15 minutes⁶⁷ (Fig. 8-8) and the response was lost equally rapidly.^{68,69} Thus the speed of the response is consistent with neural signaling. In addition, in the presence of a fourfold increase in plasma insulin and a doubling of the hepatic glucose load, the ability of portal glucose infusion to modify hepatic and muscle glucose uptake was eliminated by hepatic denervation.⁷⁰ These data provide strong support for neural involvement in the effect of the portal signal on hepatic and muscle glucose uptake.

The Afferent Limb of the Portal Signal

It is worth considering how the body monitors the difference in the arterial and portal vein glucose levels. It must first be noted that increasing the portal glucose level by infusing glucose through a peripheral vein does not trigger the portal signal. The signal is only manifest when the portal glucose level exceeds the arterial glucose

FIGURE 8-7. The portal signal is an important determinant of the disposition of a glucose load. During peripheral glucose delivery, the net hepatic glucose uptake accounts for only approximately 10% of the infused glucose, and muscle accounts for more than 50%. In the presence of the portal signal, the percentage of the glucose load taken up by skeletal muscle and liver is almost equal. (Derived from data in Adkins-Marshall BA et al: *Interaction between insulin and glucose-delivery route in regulation of net hepatic glucose uptake in conscious dogs*. Diabetes 1990;39:87.)

level, as it does during glucose feeding. It would appear that the arterial glucose level provides a reference point against which the portal glucose level can be viewed. It seems clear that the latter is perceived by the portal glucose sensors described by Nijijima and his colleagues.⁷¹⁻⁷³ It is less clear, however, where the arterial glucose level is sensed. It could be monitored in the liver, the brain, or the carotid bodies.^{17,74-76}

FIGURE 8-8. The effect of the glucose portal signal is rapid, with maximal enhancement of NHGU by 15 minutes. In contrast, the effect of insulin on NHGU is slow. When hyperinsulinemia is combined with the portal signal, the response is more rapid than the response to insulin in the absence of the portal signal. (Redrawn from Pagliassotti et al.⁶⁷)

The role of CNS glucose sensors in providing the reference information was assessed by Hsieh and associates.⁷⁶ The insulin level in conscious dogs was increased fourfold, along with a doubling of the hepatic glucose load in the presence of the portal signal to fully activate NHGU. The glucose level in the head was then increased by glucose infusion through catheters in the carotid and vertebral arteries, to a point where it was slightly above the portal glucose level. There was no impact on NHGU, suggesting that arterial glucose sensing in this context was taking place outside the CNS. Matsuhisa and colleagues¹⁷ tried a similar approach, but only used unilateral glucose infusion. They observed a small reduction in NHGU, suggesting brain sensors may be involved, but their study has some limitations⁷⁶ that prevent a definitive conclusion from being drawn. On the other hand, using similar conditions to those in their first study, Hsieh and coworkers⁷⁵ infused glucose into the hepatic artery so as to eliminate the intrahepatic arterial-portal glucose gradient. This resulted in a complete abolition of the effect of the portal signal on NHGU, strongly suggesting that the arterial-portal glucose comparison is made within the liver.

The Efferent Limb of the Portal Signal

The portal signal increased the activation of glycogen synthase in the dog and enhanced hepatic glycogen deposition in the dog and rat.^{67,77} Based on work by Shimazu and associates⁷⁸ and Jungermann and colleagues^{79,80} it appears likely that activation of the liver in response to the portal signal would involve an augmentation of parasympathetic input and/or a diminution of sympathetic signaling. Shimazu and associates⁷⁸ noted that electrical stimulation of the lateral hypothalamus (LH, primarily parasympathetic in nature) resulted in an increase in glycogen synthase activity and hepatic glycogen concentrations. Vagal, but not splanchnic, nerve stimulation produced similar effects.⁸¹ Shiota and coworkers⁸² therefore carried out a study in which they gave alpha- and beta-blockers portally, along with acetylcholine (ACh), in an attempt to examine the impact of these regulators on NHGU in conscious dogs. Insulin was increased to fourfold basal in the presence of a twofold rise in the hepatic glucose load (but without any portal glucose infusion). NHGU increased twice as much in the dogs receiving ACh and adrenergic blockers as it did in the control dogs. On the other hand, there was a marked rise in hepatic arterial flow in the experimental group that complicated data interpretation. Since no such change in hepatic artery flow occurs in response to portal glucose infusion, it raises the possibility that this effect of ACh on NHGU was associated with a nonspecific vascular event. Concomitantly, however, Stumpel and Jungermann,⁷⁹ using the perfused rat liver, also came to the conclusion that the efferent limb of the portal signal involved the parasympathetic nervous system.

Cardin and colleagues⁸³ next employed a vagus nerve cooling technique to determine whether removal of vagal efferent input would reduce or eliminate the effect of the portal signal on NHGU. Vagal cooling would reduce firing in the vagal afferents, thereby intensifying portal signaling. Thus any effect of vagal cooling to reduce NHGU would be attributable to a diminution in efferent activity and presumably ACh release. Somewhat surprisingly, vagal cooling was without effect on NHGU despite the fact that it caused a maximal increase in heart rate,⁸³ thereby validating its effectiveness. These data thus suggest that the efferent limb of the response involves a change in the level of a neural mediator other than acetylcholine. Among the possibilities are norepinephrine, neu-

ropeptide Y, and other mediators associated with the sympathetic nervous system. It thus appears at this time as if the efferent signal reaches the liver through nonparasympathetic efferent fibers.

SUMMARY

In summary, the brain has a critical role to play in maintaining blood glucose levels within narrow limits in order to promote efficient fuel metabolism and to support optimal brain function. A number of defensive counterregulatory responses that protect against falling blood glucose are initiated and/or controlled by the CNS. The exact brain areas and pathways involved in these responses have not been fully identified, but specialized hypothalamic and/or brain stem areas containing nutrient-sensitive neurons probably play an important role. In diabetes, treatment regimens with insulin or insulin secretagogues may overcome or interfere with these defenses and result in hypoglycemia. The mechanisms for these deficits in counterregulation are unknown, but it is assumed that at least part of these adaptations ultimately act to alter the function of specialized brain hypoglycemia-sensing areas.

During carbohydrate feeding it would appear that afferent nerve signaling regarding both the level of hepatic arterial glucose and the level of hepatic portal vein glucose is communicated to the CNS, where it results in a modification of sympathetic or some other input to the liver, which then activates NHGU. Many questions remain about the role of the CNS in coordinating the response of the body to nutrient intake. The significance of the portal signal in humans needs to be verified, and the nature of the afferent sensing and efferent signaling needs to be clarified. Likewise, the significance of the signal in the context of fat and protein ingestion needs to be examined. It seems clear, however, that the CNS plays an important role in coordinating the distribution of incoming nutrients to the various tissues of the body.

Stress-Induced Activation of the Neuroendocrine System and Its Effects On Carbohydrate Metabolism

Peter J. Havel

Gerald J. Taborsky, Jr.

BASIC NEUROENDOCRINE CONTROL OF PLASMA GLUCOSE

Maintenance of plasma glucose levels within a narrow range, both in the basal state and during and after meals, is the responsibility of a neuroendocrine control system. In the basal state, the basic feedback loop (Fig. 9-1) depends on the liver as a source of glucose and peripheral tissues as the site of glucose utilization. In the basal state, the brain is the most important site of utilization since it metabolizes 80% of the glucose produced after an overnight fast. Insulin and glucagon secretion from the pancreatic islet by the plasma glucose level is the major feedback regulator for maintaining glucose at steady-state levels (Fig. 9-1). Most individuals have adequate islet mass and α and β cells that have sufficient glucose sensitivity to secrete the amount of insulin and glucagon needed. Furthermore, the hepatic sensitivity to insulin and glucagon and the peripheral sensitivity to insulin are such that this amount of insulin and glucagon achieves fasting plasma glucose levels between 60 and 100 mg/dL. However, the islet, liver, and peripheral tissues are sensitive to circulating and locally released neuroendocrine controllers. Therefore, the basic islet-glucose feedback loop can be modulated by these neuroendocrine factors, which usually results, during stress, in regulation at a higher steady-state plasma glucose concentration.

MECHANISMS FOR HYPERGLYCEMIA

Due to the brain's absolute requirement for glucose, there are redundant neuroendocrine mechanisms to maintain adequate delivery of glucose to the brain between meals. Recognition that the neuroendocrine control system functions to ensure adequate glucose to maintain brain function helps one understand the mechanisms for stress hyperglycemia and their redundancy. In the simplest view there are only two ways to achieve hyperglycemia: increase the rate of glucose production by the liver or decrease the rate of glucose utilization by peripheral tissues (Fig. 9-2). Since the rate of glucose utilization by the brain is not dependent on insulin (Fig. 9-2), it is relatively constant. Thus only approximately 20% of total glucose utilization in the basal state can be modulated, and in practical terms, reduction of *basal* glucose utilization makes at most a small contribution to the *initiation* of hyperglycemia during

stress. Therefore, it is the increased hepatic production of glucose, primarily by glycogenolysis, that is responsible for the initiation of hyperglycemia during stress. Increased hepatic glucose production is characteristic of stress; for example, of the nine individual stresses discussed later in the chapter, all have increased hepatic glucose production at some point during the stress. Whether they also are characterized by fasting hyperglycemia depends on the individual stress and its effects on glucose utilization. Some stresses are characterized by impaired glucose utilization, which as the glucose level rises during stress, makes an increasing contribution to the maintenance of the hyperglycemia (Fig. 9-2). Other stresses are characterized by increased glucose utilization that nearly parallels the increase of hepatic glucose production. If glucose production and glucose utilization are increased simultaneously, then glucose turnover will increase with only minor changes of the plasma glucose level. Therefore, it is not the absolute rates of glucose production or utilization that are responsible for hyperglycemia during stress, but rather it is the imbalance between glucose production and its utilization. For this reason, it is possible for absolute glucose turnover to be increased, normal, or even decreased during stress hyperglycemia. However, total glucose turnover is usually increased during stress whether or not hyperglycemia is present. This concept is important since it is often assumed that the hyperglycemia itself is an index of carbohydrate utilization during stress. This is not the case, and recognition of this potential problem will be important to the consideration of the mechanisms for stress hyperglycemia in nondiabetic subjects and treatment of stress hyperglycemia in diabetic patients.

REGULATION OF GLUCOSE PRODUCTION AND UTILIZATION BY NEUROENDOCRINE FACTORS

Two types of neuroendocrine control factors achieve the regulation of hepatic glucose production. One type produces quick, minute-to-minute changes in hepatic glucose output. This type includes the endocrine pancreatic hormones, insulin and glucagon, and the neuroendocrine amines, epinephrine and norepinephrine (Fig. 9-3). These are short-term regulators of glycogenolysis and gluconeogenesis. Insulin inhibits hepatic glucose output from the liver, whereas glucagon, epinephrine, and norepinephrine stimulate hepatic glucose mobilization. It is the balance between these

BASAL GLUCOSE FEEDBACK LOOP

FIGURE 9-1. This basal glucose feedback loop is the underlying regulator of plasma glucose to maintain an adequate supply of glucose to the brain. Note the key role of the endocrine pancreas in this loop. (Reprinted with permission from Pfeiffer, et al.¹⁶³)

opposing factors which determines the amount of glucose that the liver produces. The second type of neuroendocrine factors determines the sensitivity of the liver to these short-term regulators of glycogenolysis and gluconeogenesis. These are the hormones cortisol, thyroxine, growth hormone (GH), and estrogens (Fig. 9-3). They alter the sensitivity of the liver to regulation by the short-term regulatory factors. Many of these long-term regulators appear to be more permissive than regulatory; that is, the pathologic excess or lack of such factors alters hepatic glucose production, but fluctuations of their plasma concentration within the usual physiologic range has no major effect.

Many of these same neuroendocrine factors are also important to the regulation of glucose utilization in peripheral tissues and thus to regulation of glucose turnover (Fig. 9-2). Insulin, epinephrine, and norepinephrine can have rapid actions on glucose utilization by affecting the ongoing processes of glucose transport without requiring changes in the rate of new protein synthesis. Cortisol, thyroxine, GH, and estrogens are slower regulators of insulin-sensitive glucose uptake, perhaps because many of their actions are mediated through gene regulation and protein synthesis. Finally, release of cytokines during certain types of stress can have direct actions on muscle to increase glucose uptake. The glu-

FIGURE 9-2. A simplified view of stress hyperglycemia. Hyperglycemia can be due to either increased glucose output from the liver or decreased use by insulin-sensitive tissues. Note that both mechanisms are usually used.

FIGURE 9-3. Neuroendocrine changes in stress hyperglycemia. Note that the basal feedback loop is modulated in the pancreas, liver, and insulin-sensitive tissues. Brain remains sensitive only to plasma glucose level and cerebral blood flow. Also note the key role of epinephrine (E) and norepinephrine (NE) in restraining the insulin response to hyperglycemia.

cose uptake of tissues such as brain, red blood cells, gut, endothelial connective tissue, and bone cells appears to be relatively insensitive to hormonal, neural, or cytokine factors. It is the glucose utilization of adipose tissue and muscle that is primarily regulated by the neuroendocrine system. Due to its mass, changes of muscle glucose utilization tend to be responsible for measured changes in whole-body glucose utilization. The glucose utilization rate of brain and the other insulin-insensitive tissues is nearly constant because this uptake process is nearly saturated at glucose levels greater than 100 mg/dL.

One important difference among these various neuroendocrine factors is the control of their secretion. Only the secretion of insulin and glucagon is sensitive to changes of plasma glucose concentration in the physiologic range. Thus hyperglycemia increases the secretion of insulin and decreases the secretion of glucagon (Fig. 9-1). Those hormonal changes will decrease glucose production by the liver and increase glucose utilization by peripheral tissues, restoring euglycemia (Fig. 9-1). Thus this feedback control system makes it difficult to achieve lasting hyperglycemia unless the sensitivity of the islet β cell to stimulation by glucose is impaired. The action of several neuroendocrine factors to decrease the β cell's sensitivity to stimulation by glucose and to decrease the α cell's sensitivity to suppression by glucose is what allows them to produce sustained hyperglycemia (Fig. 9-3).

Neuroendocrine factors can also change the sensitivity of the liver and peripheral tissues to insulin and glucagon (Fig. 9-2), but this effect by itself is not sufficient to produce lasting hyperglycemia. Again, an impairment of α - and β -cell sensitivity to glucose is required. For example, in obesity many tissues are resistant to the actions of insulin, including its ability to suppress hepatic glucose output and to increase glucose uptake in adipose tissue and muscle. Despite this impairment of insulin action, fasting hyperglycemia is not usually found in obese subjects because the islet increases its secretion of insulin. Thus the obese individual is characterized by an insulin resistance both at the liver and at the peripheral tissues that is compensated by elevated basal and stimulated insulin secretion, leading to normal basal glucose levels and normal glucose responses to ingested nutrients. This example illustrates that alterations in peripheral or hepatic insulin sensitivity, by themselves, will not necessarily lead to significant hyperglycemia unless the islet sensitivity to glucose is reduced.

GENERAL CONSIDERATIONS IN STRESS HYPERGLYCEMIA

The primary role of the metabolic response to stress is to increase substrate flux to tissues that need it. The brain is the major glucose user in the fasting state and its rate of utilization is not dependent on insulin. Therefore, maintenance of adequate central glucose delivery is solely dependent on the plasma glucose concentration and adequate cerebral blood flow. Accordingly, stress hyperglycemia can be viewed as a means of ensuring adequate delivery of glucose to the brain during stress. During conditions of normal cerebral blood flow, glucose uptake into the central nervous system (CNS) is sufficient if plasma glucose levels are above 70 mg/dL. Increased hepatic production of ketone bodies during a prolonged fast and use of ketones by the brain can reduce its obligatory need for carbohydrate by approximately 50% without interfering with neuronal function. However, any further reduction of brain glucose uptake compromises brain function and eventually leads to neuronal death. Thus, even during a prolonged fast, any compromise of cerebral blood flow will produce the need for stress hyperglycemia to compensate for a reduced rate of glucose delivery to the brain. Again, the neuroendocrine system is the key to producing this hyperglycemia. Since the brain is dependent on a continuous supply of glucose, it is not surprising that stress hyperglycemia is regulated centrally. In addition, since the CNS need for glucose is so critical, it is not surprising that redundant neuroendocrine mechanisms exist to produce hyperglycemia during stress.

Thus, there are different afferent inputs to the central nervous system that can signal the need for increased carbohydrate flux to the brain. Some of these are psychological factors involved in the perception of imminent stress. A number of others are related to physiologic factors that reflect the adequacy of substrate and oxygen delivery to the brain. These latter systems include oxygen and pH chemoreceptors in the carotid bodies, pressure sensors in the carotid sinus and the aortic arch, temperature receptors and pain receptors in the skin, and glucose receptors in the liver and brain. The signals from these peripheral receptors are carried by afferent neurons to the brain stem and relayed to higher centers where they are integrated. One of these centers, the hypothalamus, is critical for the integration and coordination of those autonomic efferent responses that influence carbohydrate metabolism and cause stress hyperglycemia. These autonomic responses stimulate hepatic glucose production, impair peripheral glucose utilization, and impair the islet responsiveness to glucose. All three changes are usually present during most types of stress, but it is the third change that is critical in allowing sustained hyperglycemia to occur. The adipose tissue hormone leptin is a humoral signal to the CNS that provides information regarding nutritional status. It also appears to regulate basal autonomic outflow and may influence the neuroendocrine response to certain stresses. Circulating leptin concentrations are proportional to body fat content, but acutely decrease and increase in response to reductions of energy intake, or overfeeding.^{1,2} Leptin receptors in the CNS are localized primarily in the hypothalamus, and leptin acts there to regulate long-term energy homeostasis via its actions to decrease food intake and increase energy expenditure.^{3,4} The effects of exogenous leptin on appetite,⁵ food intake,⁶ food-seeking behavior,⁷ and energy expenditure⁸ are more pronounced when endogenous leptin levels are low (e.g., during fasting or energy restriction) than when they are elevated (e.g., during overfeeding or obesity). Thus leptin appears to play its major physiologic role in increasing ap-

petite and decreasing energy expenditure during the adaptation to fasting or energy restriction.^{2,4}

There is also evidence that leptin has an important role in regulating the hypothalamic-pituitary-endocrine axis (hypothalamic-pituitary axis [HPA] and thyroid and reproductive axes) during its adaptation to periods of negative energy balance.⁹ For example, the activation of the HPA (via increased adrenocorticotrophic hormone [ACTH] and glucocorticoid secretion) and downregulation of the thyroid and reproductive axes (decreased thyroid-stimulating hormone [TSH], gonadotropins, and reproductive and thyroid hormones) that occur during fasting in mice are attenuated when exogenous leptin is administered to prevent the normal fasting-induced fall of circulating leptin.¹⁰ In addition, sympathoadrenal activity decreases during fasting or energy restriction in rodents¹¹ and humans,¹² and the decrease of leptin production during fasting contributes to the reduction of energy expenditure by decreasing sympathetic nervous system (SNS) outflow to brown adipose tissue in rodents.^{8,13,14} Consistent with this observation, administration of exogenous leptin activates the SNS in fasting rodents¹⁵⁻¹⁷ and non-human primates.¹⁸ Furthermore, leptin-induced SNS activation can influence glucose homeostasis at least in part through its effects on insulin and glucagon secretion.^{19,20} Although the role of leptin in mediating fasting-induced changes in neuroendocrine function is relatively straightforward, its role in mediating the effects of fasting on the neuroendocrine activation induced by stress is complex. Leptin may mediate the effect of fasting on the neuroendocrine responses to certain stresses, but during other types of stress, leptin is unlikely to have a role.

For example, cardiac surgery in humans decreases circulating leptin levels, which may in turn potentiate the HPA response to the surgical stress. In addition, patients with sepsis²¹ or burn injury²² lose their diurnal rhythm of cortisol, perhaps because of the loss of their diurnal pattern of circulating leptin. These patients receive continuous parenteral or enteral feeding, disrupting the diurnal leptin pattern that is dependent on the timing²³ and magnitude²⁴ of insulin responses to meals.

Several studies examining the role of leptin in the neuroendocrine response to stress have reported that leptin inhibits the HPA response to stress in rodents that is induced by physical restraint²⁵ or exposure to ether, but not stress induced by cold exposure.²⁶ The problem with extrapolating these results to deduce a physiological role for the fasting-induced decrease of leptin to augment HPA activation during stress is that HPA responses to many stresses are reduced, not increased, in fasted animals.²⁷

One exception appears to be the stress of neuroglucopenia. Fasting augments the cortisol and ACTH responses to the neuroglucopenia produced by insulin-induced hypoglycemia in mice.²⁸ Exogenous leptin administration inhibits those responses as well as the cortisol response to the neuroglucopenia induced by 2-deoxy-D-glucose in the rat.²⁹ In contrast, even though the sympathoadrenal (epinephrine) response to insulin-induced hypoglycemia is augmented in the fasted compared to the fed state,³⁰ leptin is unlikely to be the mediator, because during fasting endogenous leptin inhibits and exogenous leptin stimulates sympathetic outflow.

In summary, the fall of endogenous leptin may help mediate the increase of basal corticosterone and the decrease of sympathetic tone seen during fasting or energy restriction. It may also have a similar action on the HPA response to certain stresses (e.g., neuroglucopenia), but not to other types of stress. This complex interaction between the leptin system and neuroendocrine activation during stress warrants further study.

NEUROENDOCRINE SIGNALS INVOLVED IN STRESS-INDUCED HYPERGLYCEMIA

The classic description of neuroendocrine activation during stress includes increased secretion of epinephrine, norepinephrine, cortisol, GH, and glucagon, and decreased secretion of insulin. These neuroendocrine changes produce hyperglycemia by interfering with all of the important mechanisms responsible for the regulation of plasma glucose (Fig. 9-3). This neuroendocrine pattern can be reproduced by stimulation of the ventromedial hypothalamus. In nonstressed individuals, normal activities such as standing, walking, or running can also activate the sympathetic nervous system and the glucose-mobilizing hormones. As a result, there is a stimulation of hepatic glucose production. However, during these normal activities, there is not the impairment of glucose utilization in the peripheral tissues, and therefore no hyperglycemia is seen as during stress (Fig. 9-2). In fact, there is a simultaneous increase of glucose utilization secondary to increased muscular activity during exercise (Fig. 9-4). Thus hyperglycemia in such circumstances is unusual.

This form of sympathetic arousal is coordinated with muscular activity to keep the plasma glucose concentration within relatively narrow limits despite a marked increase of turnover rate (Fig. 9-4). If carbohydrate is ingested during exercise, one might expect that the exercise-induced sympathetic activation would inhibit the insulin response to the ingested glucose and thereby impair insulin-mediated glucose uptake. Thus the rate of glucose utilization might not increase enough to counterbalance the rate of glucose absorption, resulting in hyperglycemia. However, the ability of glucose to suppress the activation of the sympathetic nervous system appears to be enhanced during exercise, and prevention of the small decline in plasma glucose that occurs during strenuous exercise reduces the degree of sympathetic activation.¹ The sensitivity of the central glucose sensors is dependent on the physiologic state. Because of this increased sensitivity, carbohydrate ingestion during exercise may reduce sympathetic activation and allow sufficient insulin secretion and action to prevent hyperglycemia.

FIGURE 9-4. Basal and exercise-induced glucose turnover. A schematic of glucose production by the liver (**left arrow**), glucose use by the brain, muscle, and fat (**right arrows**), and the effect on plasma glucose concentration (**circle**) after an overnight fast (**solid lines**) and during moderate exercise (**dashed lines**). Note that during exercise there is a simultaneous increase in hepatic glucose production and muscle glucose use, so that plasma glucose level remains constant despite a marked increase in glucose turnover. The stresses of acute cold exposure and cold acclimation show a similar stimulation of both hepatic glucose production and glucose use with little change of plasma glucose level.

Exercise is an example of a situation in which activation of the somatic motor system leads to an increase in glucose removal that is independent of insulin secretion. This increase in glucose use is counterbalanced by a neuroendocrine-mediated increase in hepatic glucose production, so that plasma glucose levels remain constant despite a marked increase of glucose turnover (Fig. 9-4). In many types of stress, the same neuroendocrine activation increases hepatic glucose production (Fig. 9-5). However, without the exercise-induced increase in peripheral glucose utilization, hyperglycemia occurs (Fig. 9-5). Indeed, stress-induced neuroendocrine activation, by itself, impairs insulin secretion and impairs insulin-mediated glucose uptake (Fig. 9-3). Many stresses including hypoxia, hypotension, myocardial infarction, trauma, surgery, and the early stages of burn trauma, cold exposure, and sepsis cause impaired glucose utilization. Although different stresses can activate different afferent signals to the brain, the efferent responses usually involve sympathetic activation and increased secretion of glucose-mobilizing hormones. Thus there is a close similarity between the mechanisms for the metabolic responses to different stresses. However, as discussed below, there are real and important differences in metabolism that depend upon the particular type of stress and its etiology. Therefore, each form of stress hyperglycemia must be evaluated independently in regard to the mechanisms of its production and the rationale for treatment.

CLINICAL FORMS OF STRESS-INDUCED HYPERGLYCEMIA

Hypoxia

Acute hypoxia can produce the classic activation of the sympathetic nervous system seen during other types of stress. Both plasma norepinephrine and epinephrine are increased during acute, severe hypoxia (6–7% inspired O_2) but not during moderate hypoxia (10–12% inspired O_2).^{31,32} Thus there is a clear threshold for activation of the sympathetic nervous system by hypoxia, and

FIGURE 9-5. Hyperglycemia during hypoxia. The activation of the neuroendocrine system during hypoxia increases hepatic glucose production (**left, dashed arrow**) and increases the plasma glucose level (**dashed circle**). Hyperglycemia does not cause the expected increase of glucose use by muscle and adipose tissue (**right arrow**) because the neuroendocrine activation impairs insulin-stimulated glucose uptake. The stresses of hypotension, myocardial infarction, mild sepsis, and early burn and other types of trauma show a similar stimulation of hepatic glucose production, restraint of glucose use, and hyperglycemia.

severe hypoxia is required to produce this activation. When the hypoxia is severe, the sympathetic response to acute hypoxia is pronounced, with total catecholamine levels exceeding 1000 pg/mL. Although cytokines may be involved in mediating the sympathetic responses to certain other stresses, there is little evidence that they contribute during hypoxia. It is more likely that they are released from tissue damaged by anoxia after an episode of ischemia and reperfusion.³³ Despite the magnitude of the general sympathetic activation, the noradrenergic nerves to the pancreas are not usually activated by hypoxic stress.³⁴ In addition, the effect of sympathoadrenal activation on pancreatic hormone secretion and metabolism can be different than expected because there is evidence for β -adrenergic receptor dysfunction during hypoxia.³¹ Thus the α -adrenergic actions of circulating epinephrine and locally released norepinephrine predominate.

In addition to sympathetic activation, acute severe hypoxia can elicit the secretion of other counterregulatory hormones. Thus ACTH, glucocorticoid, and glucagon secretion are also increased. The stimulation of glucagon secretion produced by hypoxia is not mediated by the β -adrenergic action of catecholamines as it seems to be in other stresses, but rather by α -adrenergic mechanisms.³⁵ These findings are consistent with the β -adrenergic receptor dysfunction seen in hypoxia.

The inhibition of glucose-induced insulin released during hypoxia is consistent with marked sympathetic activation (Fig. 9-3). However, the inhibition is more than would be expected for the circulating levels of epinephrine. For example, epinephrine infusion in normal subjects can abolish the acute insulin response to glucose, but usually produces only a mild impairment of the acute insulin response to arginine. The marked inhibition of both glucose and arginine-induced insulin secretion during hypoxia is reminiscent of selective activation of inhibitory α -adrenergic receptors. The lack of an opposing stimulatory action of β -adrenergic receptor activation would explain the marked inhibition of insulin release seen during hypoxia. Direct evidence for such dysfunction includes abolition of the acute insulin response to isoproterenol, a selective β -adrenergic agonist, during hypoxia.³⁶ β -Adrenergic effects on other organs (e.g., lipolysis in adipose tissue and chronotropism in the heart) are also impaired.³¹

These sympathetic and hormonal changes seen during hypoxia result in insulin resistance (Fig. 9-2), carbohydrate intolerance, and hyperglycemia (Fig. 9-5). The magnitude of the hyperglycemia depends, however, on the severity of the hypoxia and the age of the subject.³¹ In animals, the threshold for the hyperglycemic effects of hypoxia are similar to those for activation of the sympathetic nervous system (i.e., a P_{O_2} of between 30 and 40 mm Hg). These hyperglycemic effects are more pronounced in the young and may help protect the developing brain from hypoxic damage.³⁷

Hypotension

During hypotension the central problem is that the blood flow decreases to the point where delivery of oxygen and substrate is inadequate to support tissue metabolic demands. Under these conditions, glucose has an advantage over other substrates since it can be partially metabolized even when tissue oxygen levels are low. However, during anaerobic metabolism of glucose, lactic acid accumulates, and this build-up is exacerbated by its reduced removal secondary to hypoperfusion. Since tissue glucose uptake is increased simply by increasing its plasma level, the hyperglycemia in-

duced by hypotension may represent a compensatory mechanism to maintain adequate fuel delivery during hypoperfusion. The pattern of increased hepatic glucose production and hyperglycemia during hypotension is similar to that seen during hypoxia (Fig. 9-5). Adequate glucose delivery is critical for both brain and cardiac function since the brain is dependent on glucose as its primary metabolic fuel and the heart becomes dependent on glucose during hypoperfusion. Despite such compensatory mechanisms, fuel delivery may still be inadequate if the hypotension is both severe and prolonged. This decompensated phase of hypotension, known as shock, is characterized by persistent vasodilation, acute respiratory distress, loss of consciousness, and multiple organ failure and death.

Hyperglycemia has been found in a number of clinical situations in which hypotension is present. For example, hyperglycemia is present in injured combat soldiers in shock, as well as in patients with heart failure and associated hypotension or shock. Although the interpretation of these clinical studies is complicated by the presence of stresses in addition to hypotension, several of these complications can be ruled out as causes of hyperglycemia. First, the moderate hypoperfusion secondary to moderate hypotension (arterial blood pressure of 50 mm Hg) is usually not severe enough to impair glucose utilization by the brain, or to impair insulin secretion from the pancreas. Second, the local and systemic acidosis seen in hemorrhagic hypotension is not responsible for the hyperglycemic response, because hypotension simulated by unloading the carotid baroreceptors, in the absence of acidosis, can also elicit substantial hyperglycemia.³⁸ Finally, it is unlikely that cytokines have a role in the hyperglycemic response to moderate hypotension, since they are only released in large quantities during shock.

Cytokines do have a role in shock, but it is related more to vasodilation. During severe shock, tumor necrosis factor alpha (TNF- α) is released from macrophages,³⁹ stimulating nitric oxide production from the vasculature.⁴⁰ This nitric oxide produces a hypocontractility of vascular smooth muscle resulting in hypotension during shock that persists despite marked sympathetic activation. Clinical studies have suggested an association between TNF- α and IL-1 levels and the multiple organ failure and mortality of hemorrhagic shock.⁴¹

The general mechanisms by which hypotension leads to hyperglycemia can be deduced by reading the available literature. Both central neural pathways and peripheral sympathetic pathways are involved. Elegant neuroanatomic studies have shown that only certain brain areas are activated during hemorrhagic hypotension, most of these in proportion to the degree of hypotension.⁴² These discrete brain areas presumably control the peripheral autonomic response to hypotension that includes activation of the sympathetic nervous system. Catecholamines have a well-recognized role in defending blood pressure. Catecholamines also contribute to the hyperglycemia of hypotension since combined adrenalectomy and splanchnic sympathectomy abolished this hyperglycemic response.⁴³

The endocrine pancreas also has a substantial role in hyperglycemia, since pancreatic hormone secretion changes in a direction that would produce glycogenolysis (Fig. 9-5) and hyperglycemia in normal animals⁴⁴ (Fig. 9-3). Insulin release is usually inhibited by hypotension, especially the insulin response to secretagogues. Since glucose is a major insulin secretagogue, such inhibition allows hyperglycemia to persist. The α_2 -adrenergic effects of catecholamines are presumed to mediate this inhibition of insulin release. If so, circulating epinephrine is the likely mediator since

the local noradrenergic nerves to the pancreas are not activated by moderate hypotension.³⁴ Indeed, elimination of the epinephrine response to hypotension by adrenalectomy reverses the inhibition of insulin release.⁴⁵ During marked hypotension, it is also possible that severe hypoperfusion of the pancreas could impair insulin secretion.

Glucagon secretion is also increased during marked hemorrhagic hypotension and undoubtedly contributes to the hyperglycemic response. This stimulation of glucagon secretion is mediated by sympathoadrenal mechanisms since combined adrenalectomy and splanchnic sympathectomy abolished this glucagon response.⁴³ Increased vasopressin secretion during hypotension may also stimulate glucagon secretion; experiments with vasopressin antagonists, which have implicated vasopressin in the defense of blood pressure during hypotension, also suggest a role for vasopressin in stimulating glucagon secretion during hypotension. Finally, both ACTH and cortisol secretion increase in response to hypotension,⁴⁶ but their role in the hyperglycemic response is unknown.

It is also important to recognize that the high levels of circulating catecholamines present during hypotension can directly stimulate liver glycogenolysis and thereby increase the plasma glucose level. There are also suggestions that vasopressin has a similar direct action on the liver. Glucocorticoids may also play an important role in allowing the liver to respond since adrenalectomy increases the morbidity associated with hemorrhage and this effect is prevented by glucocorticoid replacement.⁴⁷ Finally, hepatic sympathetic nerves may directly contribute since hepatic denervation reduces the hyperglycemic response to hypotension.^{48,49} Thus there are many mechanisms, both direct and indirect, whereby the sympathetic activation produced in response to hypotension can defend brain metabolism by causing hyperglycemia, just as it defends blood pressure by causing vasoconstriction.

Hypoglycemia

The administration of excess insulin or overproduction of endogenous insulin (e.g., insulinoma) induces hypoglycemia by increasing peripheral glucose use and by suppressing hepatic glucose production (Fig. 9-6). Because lowering the plasma glucose level

reduces brain glucose uptake and because the central nervous system is dependent on glucose as its primary metabolic fuel, systemic hypoglycemia induces a state of central glucose deficiency known as neuroglucopenia. Traditionally, central glucose receptors were thought to be the sole stimulus for activation of the neuroendocrine system. Recent evidence suggests the participation of hepatic portal vein glucose sensors.^{50,51} This activation does not produce the hyperglycemia seen in other types of stress, but rather it prevents the development of more severe hypoglycemia and eventually restores euglycemia (Fig. 9-7), by stimulating hepatic glucose production and by impairing insulin's stimulation of peripheral glucose uptake.

The neuroendocrine activation includes increased activity of the hypothalamic-pituitary-adrenal axis as reflected by increases of circulating ACTH and glucocorticoids. Hypoglycemia also stimulates the secretion of growth hormone from the anterior pituitary gland. Both glucocorticoids and growth hormone impair insulin's action to stimulate peripheral glucose uptake. In addition, glucocorticoids help sustain increased hepatic glucose production by inducing gluconeogenic enzymes. Both hormones have a relatively slow onset of action and thus do not contribute significantly to the rapid reversal of hypoglycemia⁵² (see Chap. 31). In contrast, glucagon and epinephrine have rapid actions to stimulate hepatic glucose production, and thus mediate the acute restoration of euglycemia. In addition, epinephrine, like glucocorticoids and GH, impairs insulin-stimulated glucose uptake. Available evidence suggests that glucagon is the primary factor mediating rapid glucose recovery, and that epinephrine becomes critical only when the glucagon response is impaired (see Chap. 31). Other mechanisms including the sympathetic nerves to the liver might also contribute to glucose recovery, because they are activated during central neuroglucopenia;⁵³ however, their contribution is currently unknown. The sympathetic nerves innervating the kidney are also activated during hypoglycemia⁵⁴ and may contribute to glucose counterregulation by stimulating gluconeogenesis in the kidney.

There is evidence that both the sympathetic and parasympathetic nerves that innervate the pancreas are activated during hypoglycemia, and that this autonomic neural activation, together with the sympathetic neurohormone epinephrine, mediates the glucagon response.⁵⁵⁻⁵⁷ Although it has been known for 70 years that hypoglycemia activates the adrenal medulla,⁵⁸ it has only recently been

FIGURE 9-6. Induction of hypoglycemia. The injection of large amounts of insulin suppresses hepatic glucose production (**left, dashed arrow**) and markedly increases glucose use by muscle and fat (**lower right, dashed arrow**), which combine to markedly lower plasma glucose (**dashed circle**). The fall in the plasma glucose level reduces glucose uptake by the brain (**upper right, dashed arrow**). The stress of severe sepsis produces a similar suppression of hepatic glucose production, stimulation of glucose use, and fall of plasma glucose level.

FIGURE 9-7. Recovery from hypoglycemia. The low plasma glucose level following insulin injection activates the neuroendocrine system and thereby stimulates hepatic glucose production (**left, dashed arrow**). These neuroendocrine factors also impair insulin-stimulated muscle glucose use, which helps, with the falling insulin level, to restore glucose use toward normal (**lower right arrow**). Both these effects help return plasma glucose toward basal levels (**dashed circle**).

demonstrated that hypoglycemia also activates the sympathetic nerves of the pancreas. For example, neuroglucopenia induced by administration of the nonmetabolizable glucose analog 2-deoxy-D-glucose increases the spillover of norepinephrine from the sympathetic nerves of the pancreas, demonstrating their activation during neuroglucopenia.³⁴ This activation is due to a central reflex and is specific for neuroglucopenia. Two other stresses, hypotension and hypoxia, do not increase pancreatic norepinephrine spillover.³⁴ Activation of pancreatic sympathetic nerves has also been demonstrated during insulin-induced hypoglycemia. In dogs, this activation releases the peptidergic neurotransmitter galanin⁵⁹ as well as norepinephrine from the pancreas.⁶⁰

Pancreatic parasympathetic nerves are known to be activated during the ingestion of food and this activation contributes to meal-induced insulin secretion.^{61–63} However, neuroglucopenia is the only stress known to activate the pancreatic parasympathetic nerves.⁵⁵ Current indices of the activity of pancreatic parasympathetic nerves are less direct than the use of pancreatic norepinephrine release to assess sympathetic activation. The problem is that the parasympathetic neurotransmitter acetylcholine is rapidly degraded in plasma, and therefore, its release from the pancreas is extremely difficult to measure. However, pancreatic polypeptide (PP), a peptide hormone produced by the F cells of the endocrine pancreas, is known to be under strong parasympathetic control and is therefore a useful index of the activity of pancreatic parasympathetic nerves.⁶⁴ The secretion of PP increases dramatically during hypoglycemia in rodents,^{65,66} monkeys,⁶⁷ and humans.⁶⁸ This increased PP secretion is blocked by either surgical vagotomy or cholinergic antagonists, demonstrating that the PP response to hypoglycemia is mediated by parasympathetic cholinergic activation. Thus, there is evidence that all three autonomic inputs, sympathetic neurohormone (adrenal catecholamine) secretion, sympathetic nerves, and parasympathetic nerves (Fig. 9-8), are activated during hypoglycemia.^{55,69} Furthermore, since all three autonomic inputs are known to stimulate glucagon secretion,⁵⁵ activation of these neural inputs would contribute to the glucagon response to hypoglycemia. Therefore, autonomic activation is likely to contribute to glucose recovery through the stimulation of glucagon secretion.

Despite this evidence for autonomic mediation of the glucagon response, it is known that exposure of the islet to low glucose concentrations can directly stimulate glucagon secretion,⁷⁰ even in the absence of neural activation, suggesting that autonomic neural activation may not be required to increase glucagon secretion during systemic hypoglycemia. In accord with this observation, a number of early studies, primarily in humans, did not find a significant autonomic contribution to the glucagon response to hypoglycemia.⁶⁹ In many of these experiments one or two, but usually not all three, of the autonomic inputs to the pancreas were pharmacologically blocked or surgically ablated.^{55,69} However, if there is redundancy in the autonomic stimulation of glucagon secretion, then this partial blockade would be insufficient to prevent autonomic mediation of the glucagon response.

In more recent experiments, the activation of all three autonomic inputs to the pancreas has been interrupted in order to assess the autonomic contribution to the glucagon response to insulin-induced hypoglycemia. In several of these studies ganglionic antagonists, such as hexamethonium or trimethaphan, were used to pharmacologically impair the activation of the autonomic inputs to the pancreas, because activation of all three inputs involves neurotransmission across nicotinic ganglia (Fig. 9-8). Ganglionic

FIGURE 9-8. Three autonomic inputs to the islet. (1) Preganglionic sympathetic nerves travel in the spinal cord and innervate the celiac ganglia, which supply the postganglionic sympathetic fibers that innervate the pancreas. These nerves release norepinephrine (NE), and in some species, galanin (GAL). (2) Preganglionic parasympathetic nerves travel in the vagus and innervate intrapancreatic, parasympathetic ganglia, which send postganglionic parasympathetic fibers to the islet and exocrine tissue. These nerves release acetylcholine (ACh) and vasoactive intestinal peptide (VIP). (3) Preganglionic sympathetic nerves from the spinal cord innervate the adrenal medulla and stimulate the release of the sympathetic neurohormone epinephrine (EPI), which reaches the islet via the arterial circulation. Each of these three autonomic inputs to the pancreas is activated by hypoglycemic stress; other stresses rarely activate autonomic inputs besides the sympathetic neurohormone epinephrine. These redundant autonomic pathways can be blocked (→) either at the ganglionic level by a nicotinic antagonist like hexamethonium (HEX), or by surgical disruption (X) of the preganglionic parasympathetic nerves traveling in the vagus (VAGX) and preganglionic sympathetic nerves traveling in the spinal cord (CORDX), or by lesioning the autonomic control centers in the ventromedial hypothalamus (VMHX). The islet effects of NE and ACh, but not the neuropeptides GAL or VIP, can be blocked by adrenergic and muscarinic antagonists.

blockers were found to significantly impair the glucagon response to insulin-induced hypoglycemia in dogs,⁷¹ mice,⁶⁶ and rhesus monkeys.⁶⁷ In other studies, the combined surgical interventions of vagotomy and sympathectomy in anesthetized dogs⁷¹ or electrolytic lesions of the ventromedial hypothalamus in rats⁷² markedly reduced glucagon responses to hypoglycemia. Using a different approach, it was shown that preventing central, but not peripheral, hypoglycemia impaired both parasympathetic (PP) and sympathoadrenal (epinephrine) responses and abolished the glucagon responses to hypoglycemia.⁷³ Thus, evidence from a variety of animal studies suggested that autonomic neural activation mediates a significant portion of the glucagon response to hypoglycemia.

The hypothesis of redundant autonomic stimulation of glucagon secretion during hypoglycemia has gained recent support. For example, neither methylatropine nor α - and β -adrenergic blockade alone significantly reduced the glucagon response to hypoglycemia in conscious rats, whereas together they inhibited

the response by 75%.⁷⁴ In mice, there is partial redundancy, because either atropine or combined adrenergic blockade alone significantly reduced the increase of plasma glucagon during insulin-induced hypoglycemia, whereas together they completely prevented the response.⁶⁶ Furthermore, there is also redundancy within the sympathoadrenal system itself in dogs since neither adrenalectomy nor surgical denervation of the pancreas alone inhibited the increase of glucagon secretion during hypoglycemia in vagotomized animals, but the two interventions together eliminated the glucagon response.⁷⁵ Although the older evidence for autonomic mediation of the glucagon response to hypoglycemia in humans was less compelling, studies with ganglionic blockade⁷⁶ and two studies of patients with chronic autonomic disease^{77,78} suggested autonomic mediation. Furthermore, hypoglycemia-associated autonomic failure in human subjects (see Chap. 31), which reduces both parasympathetic and sympathoadrenal (epinephrine) responses, was also shown to reduce the glucagon response to a subsequent episode of hypoglycemia.⁷⁹ In contrast, combined adrenergic and muscarinic blockade did not affect the glucagon response to insulin-induced hypoglycemia in humans,^{80,81} suggesting either that the response is not autonomically mediated or alternatively that neuropeptides, such as vasoactive intestinal peptide (VIP), participate in the neural mediation of the glucagon response to hypoglycemia. Indeed, VIP is localized in pancreatic nerves, is released from the pancreas during vagal nerve stimulation, and stimulates glucagon secretion.⁸² Classical muscarinic or adrenergic antagonists would not block the effects of neuropeptides on glucagon secretion.

More recently, a definitive study was conducted to investigate the autonomic neural contribution to the glucagon response to hypoglycemia in humans.⁶⁸ In this study the ganglionic blocker trimethaphan was infused to impair the activation of all three autonomic inputs to the pancreas in nondiabetic human subjects. Ganglionic blockade was verified by marked reductions in the plasma epinephrine, norepinephrine, and PP responses to hypoglycemia. During ganglionic blockade, the glucagon response to matched levels of hypoglycemia was reduced by 80% (Fig. 9-9). Thus this study demonstrated in humans, as previously documented in animals, that activation of the autonomic nervous system mediates the majority of the glucagon response to hypoglycemia.

Since the glucagon response to insulin-induced hypoglycemia is impaired in type 1 diabetes mellitus, the possibility that autonomic defects may cause part of this impairment has recently been suggested.⁵⁷ Alternative explanations for the impairment of the glucagon response in diabetes include impaired α -cell recognition of hypoglycemia⁸³ or defects related to β -cell loss in type 1 diabetes.⁸⁴⁻⁸⁷ The problem with the autonomic explanation is that classic diabetic autonomic neuropathy (DAN) is thought to occur primarily in diabetes of long duration (>15 years), whereas loss of the glucagon response to insulin-induced hypoglycemia can occur relatively early in the course of the disease (within the first 5 years). However, more sensitive tests of autonomic function have demonstrated autonomic impairments that occur well before the classical criteria for DAN.⁵⁷ Thus, it remains possible that the progressive loss of the glucagon response to insulin-induced hypoglycemia seen in conventionally treated patients with type 1 diabetes is related to a concomitant impairment of the autonomic inputs to the islet.

Further, with the advent of intensive insulin treatment, there appears to be a more rapid loss of the glucagon response to insulin-induced hypoglycemia. Since intensive insulin treatment is associated with increased episodes of hypoglycemia⁸⁸ and since prior

FIGURE 9-9. Pancreatic polypeptide, epinephrine, and glucagon concentrations in the peripheral plasma of seven women before, during, and after a period of 2.5 mmol/L hypoglycemia (HYPOG; vertical dashed lines) during either a saline infusion (solid squares) or ganglionic blockade with trimethaphan (open circles). (Adapted from Taborsky, et al.⁵⁷)

hypoglycemia can diminish the autonomic response to insulin-induced hypoglycemia,^{79,89,90} it appears that the rapid loss of the glucagon response to insulin-induced hypoglycemia in intensively treated patients may be secondary to a hypoglycemia-associated autonomic failure.

Finally, while marked β -cell loss is associated with rapid loss of the glucagon response to insulin-induced hypoglycemia in an animal model of type 1 diabetes,⁹¹ β -cell destruction may also be associated with loss of islet nerves. Thus, older data⁹² and very recent data⁹³ suggest rapid loss of islet sympathetic nerves in BB diabetic rats. Whether this early sympathetic islet neuropathy contributes to the loss of the glucagon response to insulin-induced hypoglycemia is currently untested, but it clearly demonstrates that not all forms of diabetic autonomic neuropathy are slow in onset.

In conclusion, hypoglycemia activates some of the same neuroendocrine mechanisms activated by other stresses. In addition, it activates both the sympathetic and the parasympathetic nerves innervating the pancreas. Evidence from experiments in non-diabetic animals demonstrates that combined autonomic activation redundantly mediates the majority of the glucagon response to hypoglycemia in a number of species. More recent evidence from human studies supports a similar mechanism.⁶⁸ The glucagon response in turn is critical for the rapid stimulation of hepatic glucose production during hypoglycemia, which helps restore euglycemia. Because the glucagon response to hypoglycemia is impaired in type 1 diabetes, autonomic defects, in addition to β -cell and α -cell defects, may contribute to this impairment.

Cold Stress

The exposure of many warm-blooded animals, including humans, to a cold environment for a period of hours (acute cold exposure) produces a neural, hormonal, and metabolic stress response that helps meet the new demands for increased thermogenesis and conservation of body heat. If the environmental challenge is not too severe and the animal's compensatory systems are intact, then a sustained fall in body core temperature will be avoided despite a lowering of skin temperature. In these animals, continued exposure to a cold environment for weeks will produce acclimation to the cold environment characterized by replacement of shivering thermogenesis with nonshivering thermogenesis. In contrast, if the cold environment is too severe or if the animal's thermoregulatory system has been impaired, body temperature will drop, resulting in hypothermia. Each of these states, acute cold exposure, cold acclimation, and hypothermia, is characterized by specific neural, hormonal, and metabolic responses. Acute cold exposure is most similar to the other acute stress states previously discussed.

Acute cold exposure activates the sympathetic nervous system as reflected by an increase of plasma norepinephrine. The activation of the adrenal medulla, however, is not a central feature of the response, being elevated primarily during more severe forms of cold exposure. Pituitary stress hormones including GH, ACTH, and TSH can be elevated if the cold exposure is severe. Surprisingly, thyroid hormones are usually not elevated despite their acknowledged role in energy production (for explanation, see below). Glucocorticoids are elevated. Acute cold exposure consistently stimulates glucagon secretion either without a significant change of basal insulin or with a significant decrease of the plasma insulin level. Acute, moderate cold exposure produces little change of plasma glucose or plasma free fatty acids despite clear increases in oxygen consumption and despite increases of both free fatty acid and glucose turnover like those seen during exercise (Fig. 9-4). More severe cold exposure can sometimes produce increases of both the plasma glucose and free fatty acid levels.

Hepatic glucose production is usually increased during acute cold exposure (Fig. 9-4). Presumably, the increase of glucagon coupled with the restraint of insulin secretion contributes to the

stimulation of hepatic glucose production. Catecholamines may also contribute, but epinephrine, the most glycogenolytic of the two major endogenous catecholamines, is usually not elevated. The sympathetic nerves of the liver may be activated,⁹⁴ as are nerves innervating adipose tissue and muscle. The increase of hepatic glucose production is usually matched by an increase of glucose utilization during cold stress (Fig. 9-4). It is likely that the shivering seen during acute cold exposure increases glucose uptake since muscle contraction, as it does during exercise, can increase glucose uptake in the absence of an increase of plasma insulin.

The increase of sympathetic nervous activity during acute cold exposure may be more related to thermoregulation than to increased hepatic glucose production. In animals that have brown fat, locally released norepinephrine can dramatically increase heat production from this tissue. In animals and adult humans who do not have brown fat, norepinephrine can still increase heat production via β -adrenergic mechanisms. Activation of the sympathetic nerves innervating skin and the extremities during cold exposure causes the peripheral vasoconstriction that is essential for heat conservation.

Chronic exposure to cold for a period of 4–6 weeks results in a sustained increase of oxygen consumption and heat production, which characterizes acclimation to the cold. However, plasma norepinephrine, plasma glucagon levels, and several other stress hormones tend to return to control levels after 4–6 weeks of cold exposure. Further, insulin secretion, which can be inhibited during acute exposure, tends to normalize during chronic cold exposure. Likewise, shivering, which characterizes the physical response to acute cold exposure, is diminished or absent during chronic cold exposure and is replaced by nonshivering thermogenesis. Although the levels of stress hormones decline during chronic cold exposure, their actions on metabolism and thermogenesis are enhanced. For example, the thermogenic response to exogenous catecholamine infusion is markedly increased in cold-acclimated animals. The role of thyroid hormones in mediating this increased sensitivity is unclear because T_3 levels are decreased in cold-acclimated humans, yet T_3 production, secretion, clearance, and turnover rate are all increased.

The increase in stress hormone secretion seen during acute cold exposure and in stress hormone action seen during cold acclimation are both impaired by hypothermia, in proportion to the decrease in core temperature. During severe hypothermia the decrease in organ temperature appears to directly suppress transmitter release from neurons, hormone secretion from endocrine glands, and substrate release from the adipose tissue, muscle, and liver. For example, hypothermia is used clinically to suppress metabolism in children during open heart surgery. A variety of measurements made in this clinical situation suggest that an impairment of insulin secretion, insulin action, and glucose metabolism leads to glucose intolerance and hyperglycemia (Fig. 9-10). However, it is not clear from these studies whether these changes of carbohydrate metabolism are due to anesthesia or hypothermia *per se*. Studies in animals have clarified the mechanisms for these effects. In general, hypothermia impairs insulin secretion. Whether or not this is a direct effect of hypothermia to induce hypofunction of pancreatic β cells or an effect mediated by circulating catecholamines may depend on the level of hypothermia achieved. For example, severe hypothermia can directly impair insulin secretion from isolated perfused pancreas, whereas the acute cold stress accompanying more moderate hypothermia increases plasma catecholamine levels that mediate a part of the impairment of insulin secretion.

FIGURE 9-10. Hypothermia and glucose turnover. The decrease of body and organ temperature during hypothermia slows all metabolic processes including hepatic glucose production (left, dashed arrow) and glucose use by both brain (upper right, dashed arrow) and peripheral tissues (lower right arrow). The plasma glucose level can be unchanged or sometimes increased (dashed circle). However, carbohydrate tolerance is always severely impaired because of the marked reduction of glucose use (right arrows).

The resistance to insulin action in hypothermic animals and humans probably has two causes: a direct suppressive effect of hypothermia on insulin-sensitive tissues dominant during severe hypothermia, and a β -adrenergically mediated inhibition of insulin-stimulated glucose uptake dominant during moderate hypothermia. This impaired insulin action, combined with impaired insulin secretion, produces severe glucose intolerance in hypothermic subjects (Fig. 9-10). Indeed, patients undergoing hypothermia for surgery become markedly hyperglycemic when given relatively modest glucose infusions. Even without exogenous glucose, most hypothermic animals and patients are at least mildly hyperglycemic despite a direct suppressive effect of hypothermia on hepatic glucose production.

During more severe hypothermia, these neural and hormonal factors may be directly suppressed by the effects of low organ temperature on secretory mechanisms. It should also be noted that anesthesia usually impairs the sympathetic activation that protects against hypothermia. This concept has two important implications. First, a level of cold exposure which would induce a stress response sufficient to maintain the core temperature in a conscious animal may result in moderate hypothermia in anesthetized animals. Second, studies of cold exposure in anesthetized animals tend to find less activation of the sympathetic nervous system, less stimulation of stress hormones and metabolism, and more direct suppressive effects of hypothermia.

Myocardial Infarction

Acute myocardial infarction (MI) has been associated with stress hormone responses and stress hyperglycemia, as in hypoxia (Fig. 9-5). Thus there is evidence that plasma catecholamines are elevated in patients admitted for MI. Although plasma norepinephrine levels can be significantly higher than controls, the epinephrine levels are more consistently elevated.⁹⁵ The elevation of plasma catecholamines is short-lived; it may normalize in 1–2 days after hospital admission. The adrenal cortical hormone cortisol is also increased within 6 hours of MI. The magnitude of the cortisol response is related to the size of the infarct and predicts mortality.⁹⁶ The mechanism for the increasing cortisol is unclear because ACTH seems to be suppressed after MI despite elevations of both arginine vasopressin (AVP) and corticotropin-releasing hormone

(CRH). Cortisol, AVP, and CRH fall toward normal between 1 and 3 days after MI.⁹⁷ GH levels are elevated for the first week after uncomplicated MI. Plasma glucagon levels are also increased after MI and insulin secretion is impaired. As expected, these changes in stress hormone levels are accompanied by either mild hyperglycemia or glucose intolerance.

The mechanism of the increase of stress hormones during myocardial infarction is multifactorial. Although it is likely that the chest pain and general anxiety experienced by a patient undergoing an acute MI contributes significantly to the sympathetic activation detected immediately after the episode, direct experimental tests of this hypothesis in humans have suggested that cardiac ischemia rather than angina increases plasma norepinephrine.⁹⁸ Nonetheless, the anxiety associated with a spontaneous MI can also contribute to the catecholamine response to MI. However, this contribution is relatively selective. Anxiety and fear usually result in increases of plasma epinephrine rather than norepinephrine. Because epinephrine is the more potent of the two endogenous catecholamines in producing hyperglycemia, the addition of significant anxiety and fear to the other factors during MI has a disproportionate influence on the amount of stress hyperglycemia produced.

In myocardial infarction patients with concomitant heart failure, the plasma catecholamines on the day of admission and the few days thereafter are markedly higher than in patients who do not experience heart failure with the MI,⁹⁵ and heart failure without MI can increase plasma catecholamines and AVP.⁹⁹ It is likely that both the increased myocardial damage associated with heart failure as well as the hypotension present in patients with heart failure contribute to the higher elevations of plasma catecholamines and AVP seen in these patients.^{95,100} In addition, the stress of hypoxia may also contribute in some severe cases of heart failure since this stress can independently activate the sympathetic nervous system and produce hyperglycemia. However, the threshold for the hypoxia-induced activation is high (see above), suggesting that severe heart failure would probably be necessary to impair oxygen delivery to the point where hypoxia *per se* would contribute significantly to the other factors that activate the sympathetic nervous system during myocardial infarction.

Recent studies suggest that cytokines are released in response to myocardial infarction, but their potential role in mediating the stress hormone response to MI has not been investigated. Certain cytokines may, however, mediate the tissue damage that is usually produced by MI. Interleukin-8 shows a transient rise during the very early phase of MI and has been suggested to attract and stimulate neutrophils, which may cause myocardial damage.¹⁰¹ IL-6 levels are also elevated in MI patients upon hospital admission, but unlike IL-8, IL-6 levels remain elevated for weeks after an MI.¹⁰² Although the role of IL-6 in MI is unclear, it does stimulate the production of certain acute-phase proteins which may predispose to coronary thrombosis. Finally, there is evidence that circulating levels of tumor necrosis factor are elevated after MI. TNF levels peak within the first 24 hours after admission, and the magnitude of the TNF response is related to the creatine kinase response,¹⁰³ an index of infarct size. The elevations of TNF may contribute to cardiac tissue damage by activating leukocytes. Other studies find elevations of TNF only in severe MI accompanied by heart failure but not during uncomplicated MI.¹⁰⁴ Thus, certain cytokines are elevated after MI. Since elevations of cytokines have been associated with the hormonal responses to other stresses, their potential role in contributing to the neuroendocrine and metabolic response to MI deserves investigation.

Although there is little debate that the release of cytokines during myocardial infarction is detrimental, the effect of neuroendocrine activation during MI can be viewed in two different ways. The potential benefit of such activation may come from the hyperglycemia subsequently produced, since the heart itself becomes dependent on glucose as fuel during periods of hypoperfusion. Additionally, MI accompanied by heart failure may produce a significant hypotension, during which increased levels of circulating glucose may compensate for the decreased cerebral perfusion rate. In contrast, others have viewed the neuroendocrine activation that accompanies MI as maladaptive. The increased circulating, and perhaps local, levels of catecholamines might increase heart rate and thus cardiac work when the delivery of the necessary metabolic fuel is already compromised. Further, elevated catecholamines increase the risk of fibrillation.

Surgery

Major surgery produces a response characterized by activation of the sympathetic nervous system and hyperglycemia (Fig. 9-5). A variety of old and new studies demonstrate that both clinical and experimental surgery increase the release of the neurotransmitter norepinephrine from sympathetic nerves and the sympathetic neurohormone epinephrine from the adrenal medulla in proportion to the severity of the surgical stress.¹⁰⁵ Surgical stress also increases the release of cortisol from the adrenal cortex. The pancreatic hormone glucagon is increased, while insulin secretion shows relative inhibition. These neural and hormonal changes are the major contributors to the elevation of plasma glucose and lactate levels seen during surgical stress.

Although it is often thought that the general anesthetics used during major surgery prevent the recognition of pain, it is clear that nociceptive stimulation is a major factor in the sympathetic activation that occurs during surgical stress. For example, early experiments in animals have shown laparotomy produces an increase of plasma catecholamines that is reversed by the analgesic morphine.¹⁰⁶ This action of morphine is blocked by the opioid antagonist naloxone. In addition, morphine does not reverse the rise of plasma catecholamines induced by central glucopenia,¹⁰⁷ demonstrating that its action is specific for nociceptive stress. Other early studies in humans suggest that activation of pain afferents during surgery causes activation of the sympathetic nervous system. For example, the catecholamine response to surgery on the lower half of the body is reduced by low spinal anesthesia,¹⁰⁸ which would be expected to block the afferent signals coming from the site of surgery but not the higher efferent sympathetic outflow. Recent studies on the effects of either high-dose opioid anesthesia or epidural anesthesia confirm and extend these findings. In brief, high-dose opioid anesthesia significantly reduces the sympathetic activation, the increase of stress hormones, and the metabolic responses accompanying cardiac bypass surgery on infants.¹⁰⁹ Likewise, the plasma catecholamine response to vascular surgery on the lower extremities is markedly reduced by epidural anesthesia.¹¹⁰ Taken together, these studies emphasize that despite the unconsciousness induced by general anesthesia, nociceptive receptors are activated during surgery and send afferent signals to the brain, resulting in a classic stress response. Opiates can block the neurotransmission of these signals either at the spinal cord or brain.

The clinical implications of these findings have only recently been recognized and documented. The evidence suggests that neuroendocrine responses to surgery are maladaptive and result in

significant morbidity and mortality. In adults, suppression of the neuroendocrine response to surgery is associated with a decreased incidence of hypertension, arterial thrombosis, postoperative cardiovascular failure, and death.¹¹¹ In newborns, suppression of the stress response decreases the incidence of sepsis, disseminated cardiovascular coagulation, and postoperative death.¹⁰⁹

Although carefully designed animal and clinical studies suggest that nociceptive activation causes a stress response during surgery, common surgical procedures are frequently much more complex, being complicated by the effects of various anesthetics as well as other stresses that are associated with particular diseases. For example, different types of anesthetics vary in their suppressive effects on the sympathetic activation and hyperglycemia produced by stress. Pentobarbital anesthesia in dogs abolishes both the moderate plasma catecholamine response and moderate hyperglycemia produced by central glucopenia in conscious animals.¹¹² In contrast, low-dose halothane, which produces full surgical anesthesia, allows both a plasma catecholamine and plasma glucose response to moderate glucopenia similar to that of the conscious animal.¹¹³ Equally important is the dose of anesthetic. Studies with halothane and other inhalation anesthetics suggest that higher doses, not surprisingly, produce a progressive suppression of certain neural reflexes, probably including the sympathetic response to surgical stress. Finally, nociception is not the only stimulus present; many surgeries are often complicated by the presence of other stresses. For example, surgical procedures that produce substantial blood loss are complicated by the stress of hemorrhagic hypotension (see above). In addition, major thoracic or abdominal surgery can produce heat loss, and since many anesthetics impair autonomic thermoregulation, mild hypothermia can result.¹¹⁴ Indeed, in pediatric cardiac surgery, hypothermia is intentional and beneficial. Nonetheless, hypothermia can be a stress in itself (see above). Also, vascular bypass operations, most notably cardiopulmonary bypass, can occasionally result in release of inflammatory cytokines associated with use of bypass pumps¹¹⁵ or the reperfusion of ischemic tissue. Finally, surgery in the gastrointestinal tract has the potential for infection secondary to the release of endogenous bacteria and endotoxins from the gut, and postsurgical infections from exogenous organisms can significantly complicate the stress response following surgery (see below).

After the surgery is over and the anesthetic has been discontinued, the stress response can in fact increase, because much of the nociceptive stimulation is still present but the suppressive effects of the anesthesia are not. Therefore, there can be a large increase in plasma catecholamines, cortisol, and other stress hormones during the immediate postsurgery period. The rapid action of catecholamines and the delayed effects of cortisol and growth hormone can sometimes lead to hyperglycemia but more often to glucose intolerance (Fig. 9-2), either of which may resolve when the nociceptive stimulation of the counterregulatory hormones wanes. Therefore, analgesics in the postoperative period would be expected to reduce plasma catecholamines,¹¹⁶ GH, and cortisol levels and accelerate the restoration of normal glucose tolerance, in addition to reducing the morbidity and mortality. Indeed, recent studies have emphasized the need and potential strategies to reduce postsurgical stress during early recovery. Several of the studies, cited above, that demonstrated low postoperative complication rates included the administration of postoperative analgesics, some under patient control. Thus, the understanding of the mechanism of the stress response to surgery is beginning to have significant clinical impact.

Sepsis

The glucose response to sepsis can be qualitatively different depending on the time elapsed since the initial septic insult and its magnitude. Sepsis quickly produces a transient hyperglycemia^{117,118} similar to that of hypoxia (Fig. 9-5), which eventually resolves. Thereafter, plasma glucose can be normal if the sepsis is mild. Despite this euglycemia, glucose utilization is usually increased^{119,117} without a significant increase of insulin. Hepatic glucose production is also increased, but the counterregulatory hormones glucagon, epinephrine, or cortisol are not. It appears that both the increase of glucose production and utilization (Fig. 9-4) may be mediated by cytokines secreted from macrophages in response to infection.¹²⁰ One such cytokine, TNF, is released in response to bacterial endotoxins and can increase the metabolic clearance rate of glucose.^{121,122} Although it may not be the exclusive mediator of the increased glucose turnover observed during sepsis,¹²³ TNF in turn stimulates the release of certain interleukins (IL-1 and IL-6) which may help mediate its hypotensive effects and perhaps some of its effect on glucose uptake.

During more chronic moderate infection, glucose production can be depressed.¹²⁴ Such depression occurs despite a doubling or tripling of glucagon, cortisol, and plasma catecholamine levels. However, the elevated level of plasma catecholamines supports even this low level of glucose production. Infusions of medium doses of TNF can reproduce these effects on glucose metabolism and counterregulatory hormone secretion.

When the infection is severe, hypoglycemia can ensue, probably due to a further direct suppressive effect of endotoxin or cytokines on hepatic glucose production coupled with a further, stimulatory effect of TNF¹²¹ and/or high plasma insulin¹²⁵ on peripheral glucose uptake. Glucose production is suppressed in this state in a manner similar to that which occurs during induction of hypoglycemia by insulin injection (Fig. 9-6). During chronic moderate sepsis, these effects occur despite increased circulating levels of glucagon and plasma catecholamines.

Although shock is widely thought to cause the mortality seen in severe sepsis, it is not well recognized that hypoglycemia can also contribute. Thus prevention of hypoglycemia by exogenous glucose infusion decreases the incidence of mortality in anesthetized animals with extreme sepsis. Animals that are able to mount a sufficient counterregulatory response to offset the suppressive effects of endotoxins and cytokines on hepatic glucose production and prevent hypoglycemia usually survive severe sepsis. Those that are not able to mount such a response die. High doses of either endotoxin or TNF,^{121,122} in addition to reproducing the hypotension characteristic of severe sepsis, can also reproduce the hypoglycemia. Furthermore, immunoneutralization of TNF reduces the lethal effect of endotoxin,¹²⁶ suggesting a pathogenic role for TNF in the fatal combination of hypotension and hypoglycemia of severe sepsis. Such studies dramatically illustrate the importance of glucose counterregulatory mechanisms in severe sepsis.

In summary, sepsis initially produces a transient hyperglycemia (Fig. 9-5) mediated by the low levels of macrophage factors released in response to the infection. If the sepsis is not quickly resolved, the secretion of the classic stress hormones is stimulated in an attempt to counterregulate the suppressive effects of accumulating levels of endotoxins and cytokines on hepatic glucose production so a precarious balance of euglycemia is struck (Fig. 9-4). As sepsis worsens and marked endotoxemia occurs, the

activity of the sympathetic nervous system and the release of glucagon and cortisol are increased further, but may be overwhelmed, producing hypotension, hypoglycemia (Fig. 9-6), and eventually death.

Burns

Major burns produce a catabolic state reflected by a prolonged increase of the resting metabolic rate proportional to the area of the burn.¹²⁷ The metabolic rate normalizes over 1–2 months following serious burns.¹²⁷ The increase in oxygen consumption is not due to increased thyroid hormone levels, which are in fact suppressed in burn patients.¹²⁷ Hepatic glucose production is also usually increased in burn victims and accounts for the 1–2 weeks of mild hyperglycemia seen after severe burns (50% or more of the body surface area)¹²⁷ (Fig. 9-11). The rate of glucose utilization is also usually elevated after burns¹²⁸; this sometimes accounts for the euglycemia seen in the face of increased glucose production following less severe burns. The turnover of gluconeogenic amino acids (e.g., alanine) is increased after burns¹²⁸ and reflects accelerated net protein catabolism in peripheral tissues. This negative nitrogen balance and the potential loss of muscle are significant clinical problems in burn patients.

Levels of stress hormones are usually elevated after severe burns. Thus plasma catecholamine levels are increased,¹²⁸ reflecting activation of the sympathetic nerves and the adrenal medulla. Both ACTH and glucocorticoids are increased markedly in burn stress¹²⁸ as is vasopressin. Baseline glucagon levels are also consistently elevated^{127,128} as are glucagon responses to the amino acid arginine. In contrast, GH and its mediator, insulin-like growth factor 1 (IGF-1), are low in burn patients¹²⁹ for unknown reasons.

It is likely that most of the stress hormones contribute in different ways to the hypermetabolism and increased glucose production characteristic of burn stress. For example, combined adrenergic blockade tends to normalize resting metabolic rate, suggesting a significant contribution of increased sympathetic tone to the elevated metabolic rate of burn patients.¹²⁴ Platelet-activating factor

FIGURE 9-11. Burn (late) and glucose turnover. After the acute stress response to burn subsides, a later hypermetabolic phase ensues. It is characterized by increased glucose production by the liver (**left, dashed arrow**) and increased glucose utilization both by muscle and injured tissues (**lower right, dashed arrow**). Increased glucose turnover is therefore present late in burn stress, usually accompanied by a mild hyperglycemia (**dashed circle**). Protein turnover is also increased, which supplies the amino acids for gluconeogenesis and tissue repair, but which also can eventually lead to muscle wasting. The stress of severe trauma can show a similar hypermetabolic phase late, after the acute stress response subsides.

(PAF) may mediate the activation of the sympathetic nervous system since a PAF antagonist reduces the plasma catecholamine response to burn stress.¹³⁰ Cytokines released from activated macrophages may contribute to the activation of the sympathetic nervous system, the increased secretion of counterregulatory hormones, and the hypermetabolism of burn stress. Indeed, plasma levels of IL-6 and IL-2 are elevated in proportion to the area of the burn,¹³¹ while elevations of TNF- α may be more related to the common complication of sepsis.¹³²

The stimulation of hepatic glucose production by elevated glucagon levels clearly makes a substantial contribution to the hyperglycemia of burn stress since suppression of glucagon secretion not only reverses the elevated rate of glucose production, but also necessitates the infusion of glucose to prevent hypoglycemia.¹²⁸ The sympathetic nervous system also contributes since PAF antagonists, which reduce the plasma catecholamine but not the glucagon response to burn stress, prevent part of the hyperglycemic response as well. Finally, the high plasma levels of glucocorticoids probably contribute to the increased glucose production, both indirectly by increasing proteolysis and thereby the plasma levels of gluconeogenic amino acids, and directly by inducing gluconeogenic enzymes. Suppressed GH secretion may allow increased proteolysis and plasma amino acid levels. Indeed, recently GH treatment has been used to limit protein catabolism¹³³ and accelerate donor skin healing.¹³⁴ Both of these beneficial effects may be due to stimulation of protein synthesis via IGF-1.¹³⁵

Despite the elevated levels of catecholamines, plasma insulin levels are normal or even elevated in burn stress. These elevated levels of plasma insulin contribute significantly to the increased glucose uptake observed in burn stress, since suppression of insulin secretion with somatostatin leads to a significant fall in the metabolic clearance rate for glucose.¹²⁸ Despite the clear effect of elevated insulin on glucose uptake, the other major anabolic effects of insulin (i.e., inhibition of lipolysis and proteolysis) do not appear to be fully expressed, as indicated by increased plasma levels of free fatty acids and increased turnover of plasma alanine. Perhaps sympathetic stimulation of adipose tissue and glucocorticoid stimulation of muscle proteolysis partially overcomes these expected inhibitory effects of insulin.

Although burn stress can be characterized by the features listed above, it is important to recognize that these responses can also be due to the presence of other stress. For example, severe burns can produce an acute shock-like hypotension, which by itself (see above) can activate the sympathetic nervous system. Indeed, volume and electrolyte replacement, which help reverse hypotension, are recognized as essential for the management of burns. In addition, the loss of large amounts of burned skin removes an important barrier to infection and frequently leads to sepsis. Recently, it has been recognized that the inflammatory response to burns itself can result in sepsis without external infection, due to translocation of gut bacteria. As reviewed above, sepsis evokes a set of stress responses that include some of those described for burn stress. Thus, the potential presence and contribution of sepsis complicates the interpretation of clinical studies of burn stress.

Trauma

Major trauma such as multiple large-bone fractures, multiple organ injuries, or head injury can quickly cause a stress response similar to those produced by many other stresses (Fig. 9-5). Later, it produces a catabolic state like that of burn stress (Fig. 9-11).

Trauma usually activates the sympathetic nervous system. In head injury patients, the degree of elevation of plasma norepinephrine and epinephrine is correlated with the size of brain injury as assessed by CT scan.¹³⁶ In multiple-system trauma, the degree of elevation of norepinephrine and sometimes epinephrine is associated with the severity of the injury.¹³⁷ Trauma acutely elevates plasma ACTH and cortisol levels, but these can normalize within a week of the injury. In contrast, GH is suppressed during major trauma,¹³⁸ as it appears to be in burn stress. The pancreatic hormone glucagon is elevated by trauma, and plasma insulin levels are depressed.¹³⁹

Trauma produces mild to marked fasting hyperglycemia, depending on the severity of the injury.^{139,140} The degree of hyperglycemia increases with the age of the subject, probably secondary to the insulin resistance found in the elderly. When mild hyperglycemia is present, there is still a large increase in glucose turnover due to elevation of hepatic glucose production that is partially offset by an increase of non-insulin-mediated uptake (Fig. 9-11). The turnover of amino acids is also increased in major trauma as it is in burn stress. This results in significant negative nitrogen balance in these patients. Studies simulating the hormonal pattern observed during major trauma suggest that the early suppression of insulin secretion significantly augments the ability of cortisol and glucagon to produce whole-body nitrogen loss.¹⁴¹ Although the role of GH in the negative nitrogen balance of major trauma has not been extensively studied, the inhibition of GH secretion during major trauma may make a significant contribution. Other stresses associated with negative nitrogen balance also have low GH levels, and GH treatment significantly ameliorates the negative nitrogen balance.¹³³ Indeed, the suggestion has been made that GH improves nitrogen balance, but probably at the expense of hyperglycemia in major trauma patients.¹³⁸

One mechanism for the stimulation of the autonomic nervous system and activation of the stress response appears to be the pain associated with major trauma. As in surgical stress, such nociceptive stimulation can lead to neural, hormonal, and metabolic responses even during impaired cerebral cortical function and loss of consciousness. In addition, if the patient were conscious, the anxiety associated with major trauma would be expected to activate the sympathetic nervous system, primarily the adrenal medulla.

Depending on the type of trauma there can be stimuli, in addition to the pain associated with the trauma, that contribute to the activation of the neuroendocrine system. These include the surgery sometimes necessary to repair organ or limb injury. Also, severe head and neck injuries can sometimes result in impaired autonomic regulation of blood pressure and body temperature, resulting in the additional stress of hypotension or hypothermia.

The stress response to major trauma can be prevented by reversing or blocking the set of stimuli specific for that trauma and its associated complications. For example, analgesics can be expected to reduce the nociceptive stimulation caused by both the original trauma and the subsequent surgery, and therefore may reduce the neuroendocrine response. Furthermore, maintenance of body temperature and blood pressure would prevent the effects of hypothermia or hypotension. However, blocking or reversing the stimuli for neuroendocrine activation is not the only way to correct the negative nitrogen balance found in trauma patients. Administering exogenous insulin would help decrease net amino acid mobilization from muscle and reduce hyperglycemia. Growth hormone administration may also decrease protein turnover and muscle

wasting via IGF-1. However, the positive effect of GH on nitrogen balance may be at the expense of further hyperglycemia, since GH directly antagonizes the action of insulin on glucose uptake.

STRESS-INDUCED HYPERGLYCEMIA IN DIABETES MELLITUS

Type 1 Diabetes Mellitus (T1DM)

Type 1 diabetes mellitus is characterized by an islet lesion leading to markedly impaired insulin secretion with eventual death and loss of almost all of the islet β cells. It often presents as diabetic coma with ketoacidosis, which was thought to indicate almost total permanent destruction of the islet β cells at the time of diagnosis. However, it is now apparent that restoration of some islet cell function is quite common. It is the restoration of this function that is responsible for the "honeymoon" phase. This restoration could be due to recovery from a virally induced or autoimmune type of injury. However, neuroendocrine findings during acute ketoacidosis suggest that a type of stress response is responsible for part of the abnormalities found in the acute ketoacidosis syndrome, and reduced neuroendocrine stress hormones may also be important to this improvement.

Elevated levels of catecholamines, cortisol, GH, and glucagon are characteristic of diabetic ketoacidosis.¹⁴² Treatment with intravenous fluids alone without insulin will reduce the hyperglycemia, fatty acid mobilization, and ketogenesis (Fig. 9-12).¹⁴³ These findings suggest that elevation of these counterregulatory hormones is responsible for converting rather severe insulin deficiency without ketoacidosis to decompensated hyperglycemia with ketoacidosis. Confirming this concept, it has been shown that β -adrenergic blocking agents are effective in reducing elevated fatty acid mobilization in ketoacidosis.¹⁴² Because many type 1 diabetic patients present to the physician without ketoacidosis, we have suggested that insulin deficiency of the magnitude usually observed is a necessary but not a sufficient explanation for the ketoacidosis syndrome. We believe that volume depletion and ac-

tivation of baroreceptor-mediated stimulation of the autonomic nervous system and the hypothalamopituitary axis are necessary additional factors in initiating ketoacidosis.

We have suggested that β -cell injury leads to impaired insulin secretion that is partially compensated by the hyperglycemia that follows. When the hyperglycemia becomes of sufficient magnitude to lead to glycosuria and electrolyte loss, it is the subsequent volume depletion associated with this excretion of glucose that activates the counterregulatory hormones epinephrine, glucagon, GH, and cortisol to produce the full-blown diabetic ketoacidosis syndrome. Of course, any other stimulus to the sympathetic system, such as trauma or burn, would lead to the same problems in under-insulinized patients. This concept may explain why low-dose insulin has become so effective in the treatment of ketoacidosis. It may be partly because such therapy is usually associated with vigorous replacement of fluid and electrolyte losses. This treatment minimizes volume depletion and restores elevated counterregulatory hormones toward normal.¹⁴³ Such fluid replacement reduces the insulin resistance induced by these hormones and possibly allows for improved insulin secretion from residual β cells. Thus, ketoacidosis in type 1 diabetes would be characterized as a sequence of events in which insulin deficiency leads to hyperglycemia, which leads to glycosuria, volume depletion, activation of the autonomic and pituitary hypothalamic axes, mobilization of fatty acids, increased hepatic glucose and ketone production, and ketoacidosis. In this context, diabetes mellitus is a form of stress, and there is a vicious cycle in which the underlying pancreatic abnormality leads to hyperglycemia, which leads to a neuroendocrine stress response, which leads to more hyperglycemia and eventual ketoacidosis. This phenomenon is more likely to occur in type 1 diabetes because of the efficient excretion of glucose in the younger age group coupled with the greater severity of insulin deficiency. In some circumstances, it would appear that ketoacidosis could occur even in the presence of "normal" levels of basal insulin being overwhelmed by increased levels of catecholamines, GH, cortisol, and glucagon. We have documented such an instance in which a patient who had basal insulin levels that were apparently normal, but in fact were low given the associated hyperglycemia (Fig. 9-13). This patient went from hyperglycemia and glycosuria without ketosis to full-blown ketoacidosis without any further change in plasma insulin.¹⁴⁴ This would seem to indicate that ketoacidosis can develop because of increased stimulation of lipolysis rather than further insulin deficiency.

Some experimental efforts have been directed to the study of whether psychologic stress can influence ketoacidosis in susceptible patients. Based upon the observation that poorly controlled type 1 diabetic patients develop elevated ketone body levels during stress interviews, two difficult-to-manage patients with recurrent acidosis thought to be related to psychological factors in their environment were treated with oral propranolol therapy.¹⁴⁵ The rationalization was that catecholamine-induced lipolysis would be prevented, so that episodes of poor diabetes control would not be associated with ketoacidosis. In these two patients, this treatment was associated with marked reduction of the frequency of hospitalization for ketoacidosis, in contrast to other forms of therapy directed at reducing the environmental stress factors in these patients' lives. This form of therapy has obvious problems because of its potential to enhance hypoglycemia unawareness in insulin-treated patients and is not recommended as therapy for such individuals. However, it does indicate, as do the findings during stress interviews, that type 1 diabetic patients are particularly sensitive to

FIGURE 9-12. The effect of intravenous fluid therapy without insulin in severe diabetic hyperglycemia. Note the marked suppression of norepinephrine (NE), epinephrine (E), and glucose (BG), indicating volume depletion as an important cause of the marked elevation of these and other counterregulatory hormones in decompensated diabetes. The levels eventually achieved by fluid therapy alone are shown as the equilibrium value. (Modified with permission from Waldhouse W, Kleinberger G, Korn A, et al: Severe hyperglycemia: Effects of rehydration on endocrine derangements and blood glucose concentration. *Diabetes* 1979;28:577.)

FIGURE 9-13. Ketoacidosis in a patient with sustained insulin secretion. Note the effect of high-dose prednisone to exaggerate hyperglycemia minimally, until insulin secretion fails to keep up between days 5 and 40. Acidosis does not develop until day 69 without any further decline in basal insulin. After splenectomy and discontinuance of prednisone, hyperglycemia completely disappeared. (Reprinted with permission from Porte, et al.¹⁴²)

activation of the autonomic and hypothalamopituitary systems. Attempts to quantitate this phenomenon in insulin-treated, type 1 diabetic patients have been made and are consistent with such a hypothesis. It has been shown, for example, that hyperglycemia induced by cortisol, epinephrine, or glucagon is exaggerated in type 1 diabetic patients, and this is particularly true during periods of relatively poor diabetes control.¹⁴⁶ For this reason, a variety of stress states are associated with increased need for insulin in such patients. It is also commonly observed that deterioration of diabetes control is likely during episodes of sepsis, burn, hypoxia, hypotension, or vascular accidents in insulin-treated diabetic patients. The presumption is that although normal subjects will have impaired insulin secretion during these stress states, the islet will tend to adapt to some degree due to the ability of β -adrenergic stimulation and glucose to modulate the α -adrenergic effects of catecholamines on the islet. Although the same adrenergic effects to increase hepatic glucose mobilization and impair peripheral insulin-mediated glucose uptake will be observed in type 1 diabetic patients, the simultaneous modulation of this phenomenon by β -adrenergic and glucose stimulation of insulin secretion does not occur, and more severe glycemia would be predicted. Treatment of these distorted relationships in type 1 diabetes mellitus will be discussed later.

Potential Role in the Etiology of Type 1 Diabetes*

Islet injury and destruction are now known to precede the onset of clinical hyperglycemia and take place over a much longer period

of time than is clinically apparent. This immune injury is indicated by the presence of islet cell antibodies and insulin autoantibodies which appear several years before the diagnosis of type 1 diabetes mellitus^{147,148} (see Chap. 20). In addition, reduced insulin responses to intravenous glucose also appear months to years prior to severe hyperglycemia.¹⁴⁹

The reasons for the activation of this destructive process are unknown but are believed to represent the activation of an autoimmune state followed by an imbalance between T-helper and T-suppressor cells and the susceptibility or resistance of islet β cells to injury.¹⁵⁰ Because some stress hormones (particularly cortisol) are known to modulate the immune system and others to alter islet β -cell activity (epinephrine, glucagon, cortisol), there has been speculation regarding the potential role of such modulation on the development and progress of islet injury.¹⁵¹ Thus, neurohormonal changes associated with stress have been proposed as one of the environmental factors that interact with hereditary factors known to be associated with risk of the development of type 1 diabetes. It has been suggested that lymphokines produced by activated macrophages and helper T cells are toxic to insulin-secreting islet β cells and therefore the regulation of antigen-presenting cells and/or regulation of helper T-cell production of interleukin (IL-1) interferon- γ (IFN- γ), or tumor necrosis factor (TNF) could increase destruction of β cells.¹⁵⁰ Hormonal regulation of suppressor cells that normally minimize or prevent immune injury is another potential mechanism by which stress hormones (particularly cortisol) and the sympathetic nerves may contribute to the likelihood of autoimmune β -cell destruction of type 1 diabetes. For example, it has been shown that suppressor T cells are more sensitive to glucocorticoids than T-helper cells.¹⁵² Thus at moderate cortisol dosages, immune injury could be increased by steroids. An example of this phenomenon may be the increased rate of development of an autoimmune form of diabetes induced in mice by low-dosage streptozocin when they are housed 10 to a cage compared with mice housed 1 to a cage, because crowded housing is associated with higher circulating adrenal steroid levels.¹⁵³ A similar phenomenon may explain why cyclophosphamide-treated NOD mice (a model of type 1 diabetes) have an increased prevalence of diabetes.¹⁵⁴ Cyclophosphamide, which is known to be an immune suppressant, markedly increases the eventual development of diabetes in this mouse model of autoimmunity and diabetes. Evidence presented so far suggests that this is best explained by postulating a toxic effect of the drug on suppressor T-cell function.^{155,156}

As an alternative, immune-related damage of islet β cells has been shown to be related to the insulin-secretory activity of these cells at the time of exposure to IL-1.¹⁵⁰ Thus, increased secretion of insulin seems to be followed by an enhanced ability of IL-1 to impair β -cell function. Because increased β -cell secretion of insulin has been found during physical stress and infection, it has been postulated that the β cells would be more sensitive to injury at these times. This increase in insulin level is usually associated with insulin resistance. Glucocorticoids, GH, and the catecholamines all cause insulin resistance, and it has been hypothesized that they are the cause of insulin resistance during stress. Because catecholamines also impair insulin secretion, the activity level of the β cell of a stressed individual can be highly varied. However, the temporal pattern of the stress response can often be characterized by an early excess of catecholamines and a late excess of glucocorticoids and GH.¹⁵⁷ Therefore, the early response to stress may be characterized by reduced insulin secretion, while the later recovery phase is often characterized by insulin resistance, and a compensa-

* Reprinted from ref. 151, pp. 533–534, courtesy of Marcel Dekker, Inc.

tory increase in β -cell activity with increased insulin secretion. In fact, studies *in vitro* and *in vivo* have suggested that the sensitivity to both immune¹⁵⁸ and nonimmune¹⁵⁹ injury may be increased when insulin secretion is increased. Thus, an alternative explanation for the increased sensitivity of crowded mice to low-dosage streptozocin discussed above could be related to an increased sensitivity of activated islet β cells to injury rather than a decrease in suppressor T-cell function. Such changes in islet β -cell secretory activity could explain why type 1 diabetes occurs with greater frequency in the fall and winter than during spring and summer. This was originally thought to be due to the increased likelihood of a specific infection that causes islet destruction, but the association is without relation to any specific infection. Thus it may be that the neurohumoral stress response to infection causes insulin resistance and increased islet β -cell insulin activity, which in turn sensitizes the β cell to autoimmune injury. The increased activity of the β cell during puberty¹⁶⁰ may provide a similar explanation for the increased incidence of type 1 diabetes in susceptible subjects at that time of life. Reducing islet number by pancreatectomy (another way of activating residual β cells) has been found to increase the likelihood of permanent diabetes in stressed rats.¹⁶¹ Thus there are a variety of mechanisms by which stress could contribute to the onset of type 1 diabetes.

A role for psychological stress in the causes and/or onset of human type 1 diabetes has also been postulated. Major life events have been found to be more frequent in diabetic children prior to diagnosis than in controls,¹⁶² but no prospective study has been carried out.

Type 2 Diabetes Mellitus (T2DM)

During this discussion of stress hyperglycemia, we have emphasized the key role that the islet β cells must play in any hyperglycemic state. Due simply to the feedback nature of islet regulation, it appears that increased hepatic glucose production and/or decreased peripheral glucose use alone or together cannot lead to sustained hyperglycemia unless the islet fails to adapt. Therefore, on theoretical grounds one would expect that hyperglycemia in type 2 diabetes mellitus must be associated with an abnormality of islet function. Nevertheless, the presence of such an islet abnormality has been somewhat controversial (see Chap. 21). This is because during standard oral glucose tolerance testing, insulin levels appear to be normal or even hypernormal in many type 2 diabetic patients. The apparent presence of normal amounts of insulin is partly related to the fact that control groups of equivalent body weight have not always been used to evaluate the appropriateness of the insulin response. In addition, insulin secretory responses to a variety of nonglucose stimulants are normal in many type 2 diabetic patients. Thus if the fasting plasma glucose level is less than 200 mg/dL, most of these patients have normal basal insulin levels for body weight, and there are apparently normal insulin responses to intravenous arginine, secretin, isoproterenol, and tolbutamide.¹⁶³ Only an abnormal response to intravenous glucose can be consistently demonstrated. However, it is now recognized that the responses to nonglucose stimulants are only normal because of the associated hyperglycemia. Thus there is a persistent and important impairment of islet sensitivity to glucose in type 2 diabetes that reduces the insulin response to all stimuli, but the hyperglycemia compensates for a reduced response to the nonglucose inputs (see Chap. 21).¹⁶⁴ Thus any stimulus that tends to impair insulin action or accelerate hepatic glucose production will be more effective in elevating glucose in type 2 patients be-

cause it would require a greater degree of hyperglycemia for the islet-cell adaptation to occur. In addition, it has now become apparent that islet β cells are probably more sensitive to the inhibitory actions of epinephrine in type 2 diabetes because the ability of epinephrine to impair islet function is also glucose-sensitive.¹⁶⁵ An increase in sensitivity to norepinephrine in type 2 diabetes has been demonstrated.¹⁶⁶ In normal individuals, the initial suppression of basal insulin by epinephrine can be reversed by a relatively modest hyperglycemia. This restores basal insulin secretory rates to pretreatment levels and modulates the hyperglycemia induced by epinephrine. In type 2 diabetes, much greater degrees of hyperglycemia are required to modulate the effects of epinephrine. Thus the same amount of stress hormone during baroreceptor, chemoreceptor, pain receptor, or psychological stimulation would be expected to produce greater increments of glycemia in such patients.¹⁶⁷ These impairments of the islet responses to glucose with their attendant effects on the sensitivity of islet β cells to nonglucose stimulants probably explains why some type 2 diabetic patients develop ketoacidosis during stress due to burn, trauma, surgery, or vascular occlusive events and transiently require insulin treatment. Not only is there increased mobilization of fatty acids from stress hormones, but there is simultaneously an exaggerated impairment of insulin secretion. After the stress activation of the neuroendocrine system is over and catecholamine and other counterregulatory hormone levels decline, these same patients may be able to maintain reasonable blood sugar levels with their usual diet or oral drug therapy.

Potential Role in the Etiology of T2DM

Studies have suggested that glucose recognition by a number of neuroendocrine cells may be abnormal and have raised the possibility that a glucose-sensing defect may be the explanation for some of the abnormal neuroendocrine findings in this syndrome.¹⁶⁸ The poor suppression of glucagon by glucose, the elevation of catecholamines unrelated to any ketoacidosis, and the supersensitivity to exercise-induced increases in GH or its paradoxical increase by oral glucose in some individuals with mild hyperglycemia may be part of the underlying disease. Although this abnormality may be due to other intrinsic structural or metabolic defects, there is also the possibility that neuroendocrine factors known to influence the islet response to glucose are also involved. Thus, increased insulin release may be observed in type 2 diabetes during the infusion of the α -adrenergic receptor blocking agent phentolamine, implying increased α -adrenergic receptor activity or sensitivity in such subjects.¹⁶⁹

We have shown that infusion of a synthetic somatostatin analogue in dogs produces hyperglycemia and selective impairment of glucose-induced insulin release quite analogous to that found in type 2 diabetes.¹⁰⁶ A similar phenomenon has been observed with infusion of the neuropeptide galanin, which is present in pancreatic nerves of some species.¹⁷⁰ Thus a variety of inhibitory β -cell neuroendocrine factors can produce a syndrome that resembles type 2 diabetes. A mouse model of diabetes and obesity (ob ob) has been found to be supersensitive to catecholamines and stress. It has been suggested that this change is a key factor in the development of diabetes in this animal model.¹⁷¹

Although none of these findings are conclusive, it is apparent that activation of neuroendocrine systems that impair glucose sensitivity of the islet β cell can produce a syndrome quite similar to type 2 diabetes. There is accumulating evidence that such activation may be an important part of the hyperglycemia observed in type 2 diabetes. Regardless of etiologic considerations, it is clear

that stress hyperglycemia in such patients is almost certain to be more severe and to be less well counteracted than in normal subjects. This will have important treatment and therapeutic implications, which will be discussed later.

CLINICAL MANAGEMENT OF STRESS-INDUCED HYPERGLYCEMIA

Normal Subjects

Metabolic adaptation to an environmental stress may be beneficial or harmful. The stress responses that occur in normal animals or humans are not necessarily beneficial for long-term survival. In fact, maladaptive responses may be a significant cause of long-term morbidity and mortality in humans. Recommendations for the treatment of stress hyperglycemia must be based on the concept that the hyperglycemic response is more harmful than helpful. This determination will vary with the clinical state and with the degree of hyperglycemia observed. Because the central nervous system is dependent upon maintenance of at least 50% of its usual basal glucose flux, assessment of CNS needs for glucose and its adequate provision is a key determinant of treatment. Thus, glucose concentration, cerebral blood flow, and cerebral oxygenation are all critical parameters to be evaluated. One of the most efficient ways of increasing glucose flux to the central nervous system is to increase its concentration in the circulation, and this presumably underlies the biologic response of stress hyperglycemia. It is not possible to increase this flux by increasing insulin because the uptake of glucose by the CNS is insulin-independent. Therefore, if insulin is administered and plasma glucose levels fall, CNS use of glucose will remain stable or decline. In hypovolemic and hypotensive states, in patients with cerebrovascular occlusive disease or with myocardial infarction and low cardiac output, or in hypoxic states, reversal of the hyperglycemia is contraindicated unless the plasma glucose levels rise to what are considered to be toxic levels. What must be kept in mind is that the delivery rate or flux of glucose provided to the central nervous system and not the glucose level is the key parameter that will determine the adequacy of fuel delivery. In the absence of significant glycosuria and/or electrolyte imbalance, detrimental effects of hyperglycemia are minimal, and short of these complications, hyperglycemia in such states should not be treated because it is enhancing glucose delivery to the central nervous system.

In conditions in which nutrient need in peripheral tissues is increased—such as burn, trauma, or cold stress—and when there is no reduction of flow or glucose delivery to the central nervous system, hyperglycemia is not necessary for high rates of glucose uptake. In these instances, the need for carbohydrate is related to a general need for substrate by injured body tissues, most of which are insulin-sensitive. Thus, the delivery of glucose can be accelerated by the use of insulin alone or with glucose without depriving the CNS of adequate fuel. In this case, the potentially harmful side effects of glycosuria, electrolyte loss, hyperosmolarity, and increased gluconeogenesis can be avoided. In patients with myocardial infarction, it has been suggested that the ischemic myocardial tissue may benefit from increased glucose uptake and decreased fatty acid mobilization.^{172,173} When one administers insulin, it must be remembered that as the blood glucose falls, those tissues that are insulin-insensitive will receive less glucose. Therefore, cerebral blood flow needs to be assessed to be sure that it is adequate before giving insulin to patients with MI. It is likely that the injured heart tissue remains insulin-sensitive, and therefore glucose uptake by

cardiovascular muscle is likely to increase despite a decrease of plasma glucose. However, this is not known for certain, and it may be advisable to give glucose along with the insulin to maintain significant amounts of hyperglycemia while accelerating glucose uptake in insulin-sensitive tissues.

One must remember that under these circumstances potassium uptake will also be accelerated. Any change of serum potassium may influence cardiac contractility or cardiac rhythmicity. Thus the use of glucose, insulin, and potassium solutions has been recommended, but there are potential risks as well as benefits. Because simple elevation of plasma glucose levels may not be effective in increasing glucose uptake in an insulin-sensitive tissue in the absence of additional insulin, provision of insulin may be critical. Thus the elevation of catecholamines during infarction may be playing a critical role in limiting the uptake of glucose by the heart. Insulin treatment may be simply reversing an insulin deficiency state. This issue is still at present unresolved, and therefore the level of glucose and or the level of insulin may both be important. This may even vary from patient to patient and could explain some of the controversy regarding the benefits of such therapy.

Some forms of stress hyperglycemia are characterized by hyperglycemia that appears to be of no useful purpose. That is, the hyperglycemia appears to be an unnecessary response to a perceived threat, which in primitive humans might have been associated with increased muscular activity and nutrient demand but is not so in present circumstances. This leads to an imbalance between an increased glucose production and unaltered use, leading to hyperglycemia. This would also be true of most pain-related syndromes, particularly those in which significant amounts of trauma have not occurred and there is no need for increased glucose use or nutrient support for injured tissues. This can be the case in the postoperative period after surgical procedures in which tissue damage or injury has been relatively minor. Treatment under such circumstances is indicated whenever hyperglycemia is severe, and there appears to be no real contraindication. A similar situation occurs in hypothermia in which total body metabolism is reduced. In the absence of extra glucose administration, hyperglycemia is unusual. However, if glucose is given to hypothermic humans, rather severe hyperglycemia can occur. In this case, treatment to reduce this glucose level is unlikely to have any harmful side effects. Usually all that is necessary is to stop the administration of exogenous glucose. More important is the prevention of this hyperglycemic syndrome by not giving glucose to hypothermic patients.

In summary, treatment of stress hyperglycemia resolves itself into three separate approaches: (1) maintenance of the hyperglycemia for those conditions in which there is a real or potential deficiency of central nervous system uptake that can be reversed by maintaining or even increasing the hyperglycemia; (2) increasing glucose turnover by administering glucose and insulin or insulin alone, for those conditions in which an increase of glucose use by insulin-sensitive tissues is desired; or (3) no treatment in those conditions in which there is no change of nutrient need. If hyperglycemia becomes severe, it can be treated with insulin alone, because the extra glucose being produced is not providing any needed function.

T1DM Patients

General treatment concepts in type 1 diabetic patients are no different than those in normal subjects. Stress hyperglycemia in the diabetic patient has the same implications as it does in the normal

population, but there are circumstances during which euglycemia is not desirable and hyperglycemia should be promoted. Again, these are conditions in which central nervous system glucose uptake is impaired. This includes hypoxia, hypotension, cerebrovascular occlusive disease, and cardiovascular states in which reduced cerebral blood flow is present. Under most conditions, hepatic glucose production will increase and hyperglycemia will be present despite the administration of the usual amounts of insulin. However, this may not always be the case, because there may be simultaneous reduction in nutrient intake, and a considerable amount of insulin administration is related to nutrient ingestion. Therefore, it may be necessary to reduce insulin dose in type 1 diabetic subjects during this form of stress.

In burns, trauma, MI, or surgery related to trauma or in which traumatic injury is likely to be extensive, the need for increased nutrient delivery to peripheral tissues in a type 1 diabetic patient is similar to that in normal subjects. Again, the need for increased substrate use may be severe, and although euglycemia may be achieved by reducing caloric intake, this is not the desirable treatment. As in the normal individual, carbohydrate, fat, and protein either orally or intravenously should be given along with sufficient additional insulin to maintain euglycemic levels. Thus, in conditions in which catabolic protein loss is undesirable and gluconeogenesis is to be suppressed, sufficient exogenous calories should be given to meet metabolic needs even if these are increased over basal levels. In order to suppress hepatic glucose production, it may be necessary to administer large amounts of intravenous carbohydrate. If hyperglycemia occurs, then additional insulin should be given along with the additional carbohydrate rather than restricting carbohydrate calories, because the goal is to promote nitrogen uptake in injured tissues while sparing protein resources from gluconeogenesis.

In trying to anticipate insulin need during surgical procedures, a number of approaches have been taken. In general terms, insulin should be administered as a basal amount plus an amount in proportion to expected caloric intake. Basal insulin needs are real, and therefore insulin should always be administered every day. In uncomplicated surgical procedures, we have tended to reduce long-acting insulin to approximately 50% of the usual dose and to cover additional caloric need by monitoring plasma glucose before and after the surgery. Plasma glucose levels are to be maintained between 150 and 200 mg/dL. Under complex surgical conditions, long-acting insulins have not been used, and the patients have been switched to six hourly injections of subcutaneous regular insulin or to continuous intravenous insulin infusion along with sufficient carbohydrate to provide at least 600 cal/24 h, preferably 1000 calories or more per 24 hours (see Chap. 37). Insulin dosage must be individualized because insulin sensitivity varies considerably from patient to patient. Because counterregulatory hormones are suppressed by many anesthetics, it may be the postoperative phase in which insulin resistance will be most severe. Normal prehepatic basal insulin secretory rates for a lean individual are approximately 15–25 U/d in the basal state. One can estimate insulin need on the basis of this requirement. Approximately an equal amount of insulin appears to be required to maintain normal glucose homeostasis during the provision of a 2000- to 2500-calorie diet. These considerations can lead to rough estimates of insulin need in lean type 1 diabetic patients to be 40–50 U/d.

The major problem in type 1 diabetes is the inability to anticipate the impact of neuroendocrine control mechanisms upon plasma glucose. It is clear that stress produces increased glucose

levels and a tendency towards ketosis in poorly controlled type 1 diabetic patients. In some patients, the impact of the environment seems to be particularly important in the regulation of plasma glucose. Whether some individuals are particularly sensitive to environmental influences, whether individuals vary widely in their autonomic and hypothalamic responses to perceived injury, or whether there is wide variability in the sensitivity of various individuals to catecholamines, cortisol, or GH is unknown. However, it is clear that it is difficult to predict in any patient what emotional trauma or surgical stress will produce in the way of altered glucose homeostasis. As mentioned earlier, in a few instances it has been possible to ameliorate severe psychological stress by treating patients prophylactically with propranolol to prevent recurrent episodes of ketoacidosis. Treatment with other types of more selective blocking agents in an attempt to improve diabetes control has not been attempted as yet. However, the emphasis on improved diabetes control by the use of open-loop insulin infusion devices would seem to require not only careful control of nutrient intake but attempts to modify autonomic influences on carbohydrate metabolism as the other major area of therapeutic intervention that will need to be addressed. The recent recognition of hypoglycemia-associated autonomic failure (see Chap. 31) has revealed that autonomic counterregulation may be expected to vary from day to day in some patients. Thus autonomic excess and/or deficiency may be quite common and contribute significantly to hypo- and hyperglycemia.

T2DM Patients

In type 2 diabetes, plasma glucose is reregulated to a stable level which is greater than in the normal population. However, the usual regulatory mechanisms for maintaining a constant plasma glucose level remain intact although impaired. That is, insulin secretion is still present, and it responds to glucose. The sensitivity of this response is reduced, and therefore any nutrient challenge or challenge from an increased output of counterregulatory hormones will result in greater degrees of hyperglycemia for longer periods of time. However, as in the normal individual, these mechanisms will tend to stabilize plasma glucose levels even during stress. Thus with mild forms of stress, the reregulated plasma glucose level will tend to remain constant. The degree to which hyperglycemia will be increased by a particular stress in a type 2 diabetic patient is difficult to anticipate. This is because it will depend upon the sensitivity of that individual to all of the stress-related hormones, the basic nature of his or her islet impairment, and the responsiveness of the counterregulatory hormones to the stressful event. Very little is known regarding changes in sensitivity or responsiveness of this system in type 2 diabetes; however, there are studies suggesting that psychological stress may increase plasma glucose.¹⁷⁴ Nevertheless, because glucose sensitivity of the islets is clearly impaired and many of these subjects are insulin-resistant to begin with, it seems clear that greater degrees of glycemic increments are going to occur if the stress produces similar elevations of stress hormones. Presumably, this sensitivity will depend upon the degree of hyperglycemia prior to the stressful event. Individuals under relatively poor control will therefore be expected to become much worse and perhaps be unable to reregulate due to the increased glycosuria. If so, volume depletion and increased stress hormone responses will occur. This is presumably the explanation for the development of ketoacidosis during sepsis, trauma, and surgical interventions in relatively poorly controlled type 2 diabetic patients (see Chap. 34). On the other hand, the use of oral hypoglycemic

agents to lower plasma glucose and to improve islet function and peripheral sensitivity to insulin results in a patient who has reregulated plasma glucose to a more normal value. In this case, it has been the general experience that maintaining the individual on oral agents allows reasonable responses to the modest stress associated with elective surgical procedures, without the need to switch to insulin (see Chap. 37).

Thus, the major treatment decision that must be made in the type 2 diabetic patient is whether or not to stop an oral agent and to institute insulin treatment. Well-controlled patients will manage quite well during elective surgery and other minor stressful situations. However, in any poorly controlled patient during episodes of bacterial sepsis, MI, burn, major trauma, and so on, the stress response may overwhelm the islet or produce a stimulus that is beyond the ability of the impaired islet to counterregulate. Thus, severe degrees of hyperglycemia and ketoacidosis are not uncommon in type 2 diabetes during stress and may even occur in normal individuals with very severe stress. In this case, insulin treatment must be instituted. Insulin treatment should be given to any poorly controlled patient who is about to go to surgery or to any patient if a major traumatic event can be anticipated, such as a major surgical procedure. The treatment of such patients with insulin does not predict that they will require insulin after the stressful period. Thus, the discovery of severe hyperglycemia and even ketoacidosis during stress in an individual who on clinical grounds would be suspected of type 2 diabetes (onset over age 50 or a major degree of obesity) does not indicate the permanent need for insulin. Such patients may respond quite well to the usual therapeutic approaches to type 2 diabetes when the stressful event is over. Once the decision has been made to treat a type 2 diabetic patient with insulin, then the evaluation and treatment of stress hyperglycemia is similar to that for the type 1 diabetic patient discussed earlier.

SUMMARY AND CONCLUSIONS

Neural regulation of the pancreatic islet in conjunction with other hormonal glucoregulatory systems is an important component of plasma glucose regulation, which contributes significantly to the normal disposition of exogenous nutrients and to defining the glycemic response to environmental stress. The neuroendocrine system tends to modulate the intrinsic regulatory control system for plasma glucose, which involves the liver, peripheral tissues, and the islet as the primary nutrient and substrate sensors. The sensitivity and function of all three elements of this system are responsive to neuroendocrine control. Neural and endocrine influences are important to hepatic glucose production and to the use and disposition of fuels in adipose tissue and muscle, as well as to islet function. Stress responses that occur in normal animals or humans may or may not be beneficial for long-term survival. Thus evaluation of the impact of the hyperglycemia found under such circumstances must be made prior to a treatment decision. Although maladaptive responses may be a significant cause of long-term morbidity and mortality in humans, there are many circumstances under which hyperglycemia may be beneficial or even essential for survival. Treatment will depend on which category of hyperglycemic response one can place the particular patient into. Is this hyperglycemia related to the need for the central nervous system to increase glucose uptake and substrate utilization? Is this hyperglycemia related to a need for peripheral tissues to increase glucose

uptake for repair or anabolic processes? Or is this hyperglycemia an inappropriate or excessive response to some perceived or actual threat from the environment in which the hyperglycemia is useless or perhaps even detrimental to health? This will be a critical decision affecting treatment.

A number of physiologic and psychological types of stress have been discussed, and it is clear that although there is a general pattern to the neuroendocrine changes found, each stress state represents a unique set of circumstances with specific metabolic disturbances. At times it is difficult to distinguish the stress response of a normal individual from idiopathic diabetes mellitus, particularly type 2 diabetes mellitus. In the short term, the therapeutic decision is not related to the etiology of the hyperglycemia, but in the long term this may be a critical issue in the development of a suitable treatment protocol. Thus treatment considerations vary from patient to patient and depend upon the nature of the stress and the specific response to that stress in the individual case. Associated conditions play an important role in this evaluation. In the final analysis, the question that must be asked is, "Is the hyperglycemic state more harmful than helpful and will the contemplated treatment be beneficial and decrease risk?" An understanding of the neuroendocrine response system for stress and its actions upon substrate-using systems is an essential prerequisite for this decision. In diabetes mellitus, neuroendocrine abnormalities are common. Even in the apparently unstressed individual, increased sensitivity or increased levels of stress-related hormones and neural inputs may contribute either etiologically or pathophysiologically to the hyperglycemia observed. At times, a pathophysiologic separation of stress hyperglycemia and type 2 diabetes is not possible. Both involve alterations of the regulation of hepatic glucose output and peripheral sensitivity of tissues to insulin, as well as alterations of islet function. Therefore, regardless of etiologic significance, neuroendocrine control systems must be taken into account in the diagnosis, evaluation, and treatment of any hyperglycemic state in humans.

Food Intake and Energy Balance

Stephen C. Woods

Michael W. Schwartz

INTRODUCTION

Over the past two decades, knowledge of the biological controls of eating and the regulation of body adiposity has advanced at an unprecedented pace. This denouement of sorts is due in part to technological innovations that enable us to probe the workings of individual cells and molecules, as well as to an enormous investment of funds for basic research by government and industry. While this explosion of new information may one day lead to novel therapeutic approaches that limit energy intake^{1–7} and thereby lower body weight, the prevalence of obesity continues to increase in spite of this wealth of new information, as does the incidence of obesity-related health consequences including non-insulin-dependent diabetes mellitus or type 2 diabetes mellitus (T2DM).⁴ Our intent in this chapter is to summarize and discuss what is new and exciting in the realm of the neuroendocrine control of energy homeostasis, focusing on food intake, and to suggest avenues for novel therapeutic strategies.

FOOD INTAKE

Food intake is a complex behavior with multiple levels and kinds of regulatory control.⁸ In addition to providing the calories necessary to enable the body to grow and function, food also provides appropriate micronutrients (vitamins and minerals), macronutrients (carbohydrates, fats, and proteins), and a certain amount of water. Food intake occurs in distinct bouts or meals, and different controllers influence the onset and the offset of meals. Food intake addresses acute energy needs as well as long-term energy storage as fat depots. Finally, whereas regulation of food intake is related directly to energy or caloric homeostasis, food intake is also influenced by other kinds of needs. For example, when individuals are ill or incapacitated, or preoccupied with other behaviors, they often eat less food despite the stimulus of reduced fat or reduced fat stores. The integration of all of these needs relies upon neural and hormonal signals arising in many sites within the body and impinging upon regulatory control areas of the brain. As discussed below, many signals important in the regulation of blood glucose are also critical to the regulation of energy intake. In this chapter, we focus

first on the control of individual meal initiation and cessation, and later on the complex array of neuropeptides (as well as other neurotransmitters) thought to be important in the overall regulation of energy stores.

MEALS

Most animals, including humans, adopt an eating schedule that accommodates their idiosyncratic environmental conditions. In most individuals, distinct patterns can be discerned (e.g., consuming three meals a day, at the same time each day). However, because obligatory activities (such as working or going to school) and constraints (the probable presence of predators at certain times of day for some species) vary widely among individuals, most adapt by developing unique eating patterns (the size and timing of meals) that provide necessary nutrients and otherwise optimize fitness.⁹ In spite of this variation among individuals, most members of a species develop and maintain a rather consistent body weight as adults,^{10–12} and this is also true of humans. The control system that allows meal patterns to vary while adjusting daily caloric intake to meet energy needs and maintain body weight is elegant. A key feature is that whereas meal size has been found to be controlled by physiologic signals important in energy homeostasis, meal onset has not (see below). Hence, meals can be initiated at times that are convenient, or that have proven successful in the past, or that are imposed by the environment, and the individual is still able to obtain and eat adequate calories each day to maintain his or her weight. The explanation, as documented below, is that if an individual's weight begins to decrease slightly, he or she will eat larger meals when the opportunity arises and thereby regain lost weight by increasing meal size. Conversely, an individual whose weight begins to increase due to overconsumption of food will tend to eat smaller meals until the increment is lost.

Meal Initiation

Historically, the prevailing belief was that meal initiation (and perhaps its subjective analogue, hunger) is regulated by important changes in key metabolic parameters. Early in the 20th century, Cannon and his colleagues postulated that contractions of the

stomach signaled dwindling energy supplies and compelled an individual to seek and eat food.¹³ The concept of "hunger pangs" emanating from the stomach has considerable face validity and has persisted in common parlance in spite of a wealth of evidence indicating that, if anything, signals related to gastric contractions are more numerous and robust after rather than before meals. Further, individuals who are incapable of sensing stomach contractions experience normal hunger and meal initiation. Perhaps the most popular belief concerning the cause of meal initiation was based on Jean Mayer's glucostatic hypothesis. Early in this century blood glucose was thought to be a critical determinant of meals,¹⁴ and this concept was formalized and popularized by Mayer.^{15,16} In its original version, the glucostatic hypothesis stated that hunger and eating are initiated when blood glucose decreases to a threshold level, and meals are terminated when blood glucose returns to a higher and hence safer level. Later versions of the hypothesis recognized the fact that individuals with type 1 diabetes mellitus (T1DM) have both elevated blood glucose and hunger and food intake. Hence the predominant incarnation of the hypothesis is that meal onset and offset are determined by the level of metabolic utilization of glucose by sensory cells located in the hypothalamus. These glucose-sensing cells were postulated by Mayer to be insulin sensitive. It is now recognized that there are glucose-sensitive neurons in many places in the brain, including the hypothalamus, and that some of these in turn are in fact also sensitive to insulin.¹⁷ Recent evidence also indicates that the level of circulating glucose is detected by sensory nerves located in the hepatic portal vein and that the signal is relayed to the brain via the vagus nerves.¹⁸

It is reasonable to speculate that the tendency to take food would be linked causally to the ebb and flow of metabolic fuels in the blood. That is, when readily available energy becomes relatively depleted from the blood, potentially threatening the ongoing nourishment of critical tissues, eating is initiated and the circulating energy supply becomes repleted. "Depletion-repletion" logic has been applied successfully to the understanding of water and salt ingestion as they apply to the maintenance of blood volume.^{19,20} A key point, however, is that under usual circumstances, the supply of energy in the blood does not decrease to anywhere near the threshold necessary to trigger eating. Rather, individuals initiate meals even though ample energy is readily available. It is true that if the amount of energy derived from glucose is greatly decreased, either by drugs that deplete it from the blood (exogenous insulin²¹⁻²³) or drugs that prevent its cellular oxidation (e.g., 2-deoxy-D-glucose, or 2-DG^{21,24}), an emergency situation occurs as the brain detects its requisite fuel supply dwindling. One result is that animals seek and ingest food.²⁵ Likewise, if fat utilization is experimentally compromised,^{26,27} the source of usable fuel by the liver is challenged, the liver sends critical neural messages to the brain, and animals also seek and ingest food.^{25,28}

Several observations argue against the notion that meals are triggered in response to depletion of metabolic substrates. Eating is in fact a relatively inefficient way to get calories into the blood rapidly. Unless pure glucose is available (rare in natural settings), foods must be processed and digested in the stomach, passed to the intestine where they are further processed, and then absorbed into the blood. When the glucose supply to the brain is compromised by administering insulin or 2-DG systemically, the initial response is increased glucagon and epinephrine secretion.²⁹ Hence the first line of defense is to mobilize stored carbohydrate. Eating also occurs, but after a considerable lag.²¹ In this light, the induced eating can be considered more as a hedge against future excursions of

hypoglycemia than as a means of reversing the present one. It also seems maladaptive to require an individual to attain dangerously low levels of glucose prior to the initiation of every meal, nor is it clear what the consequences would be if glucose availability dipped to the threshold for initiating meals at a time when it was inconvenient or impossible to eat. It is now generally recognized that this protective system is probably activated to the point of initiating a meal only in extreme metabolic emergencies rather than as part of normal food intake regulation.^{21,25,30}

In spite of the contrary evidence, the glucostatic hypothesis has enjoyed tremendous popularity over the years. Renewed interest in the hypothesis arose when it became possible to monitor blood glucose continuously by means of an indwelling intravenous catheter. Using this technique, Campfield and Smith^{31,32} observed that blood glucose starts decreasing beginning a few minutes prior to the initiation of "spontaneous" meals in freely feeding rats. More recently the same researchers reported a similar phenomenon in humans.³³ This is an important observation because, at least in rats, every observed spontaneous meal was preceded by the small (approximately 12%) but reliable decline of plasma glucose.³⁴ The premeal decline of blood glucose reverses just prior to the actual initiation of eating, and if food is removed at that point (and no eating occurs), glucose returns to the baseline that was present before the decline began. Campfield and Smith have interpreted the premeal glucose decline as providing a signal that is monitored by the brain.^{32,35,36} When the parameters of the decline are "correct," a meal is initiated. If metabolic conditions preclude the decline meeting the "correct" parametric criteria, no meal is initiated. In their schema, Campfield and Smith believe that the brain is the initiator of the decline of plasma glucose. Consistent with this, there is a small increase of plasma insulin at the start of the premeal decline of glucose which is dependent on an intact vagus nerve,^{31,32} and cutting the vagus disrupts the relationship between changes of glucose and the start of meals.³⁵ This body of research suggests that small, physiological fluctuations of glucose can provide important signals that the brain uses to help determine ingestive responses.

Analogous to decreases of blood glucose, other metabolic events occur prior to, and hence are predictive of, the onset of meals. Implanted thermistors allow body temperature to be monitored continuously in freely moving and feeding animals. Just prior to spontaneous meals, the body temperature of rats begins to increase.³⁷ When the meal begins, temperature continues to increase and then declines as the meal is terminated. Likewise, metabolic rate as assessed by indirect calorimetry reportedly decreases prior to the start of spontaneous meals, and increases as eating begins.^{38,39} All of these parameters (blood glucose, temperature, metabolic rate, and no doubt others as well) begin a gradual change 10–15 minutes before meals begin, and all are therefore highly correlated with meal onset. With a slightly different time course, laboratory rats increase their activity (e.g., running in a wheel) prior to spontaneous meals.⁴⁰⁻⁴³ These phenomena have generally been viewed as supporting the hypothesis that animals eat because these changes are occurring; i.e., that the decrease of blood glucose or of metabolic rate, or the exercise-induced use of fuels, is causally related to meal onset. However, a compelling case can also be made that, based on factors such as habit or opportunity, other factors determine when a meal is going to start, and that as part of the overall meal initiation process the brain elicits metabolic changes to prepare the body to receive the food.^{44,45} As an example, a premeal decline of blood glucose can limit the magnitude of the otherwise much larger postprandial increase of blood glucose.

In this schema, individuals do not initiate meals because one or another tissue's supply of available energy is about to be compromised, but rather one eats in response to learned cues and various environmental or sensory stimuli. The timing of meals can therefore be quite idiosyncratic and dictated by an individual's lifestyle, convenience, and opportunity. This schema can account for the extreme variability of meal patterns among individuals in a society, but it cannot in itself account for the remarkable ability of individuals to maintain neutral energy balance and a constant level of adiposity.

To summarize, although it is possible that meal-related fluctuations in blood glucose and other parameters are the initiators and terminators of meals, the bulk of evidence is to the contrary. The brain and liver are quite efficient at controlling the provision of what is needed by various tissues, and as a result adequate amounts of utilizable fuels (glucose and fats) are generally always available to tissues via the blood. Major fluctuations in the circulating levels of these fuels generally occur only during and after meals, as ingested energy passes from the gut into the circulation, and from the circulation into tissues and energy storage organs. Decreases of plasma fuels below levels adequate to meet tissue requirements are rare in normal, free-feeding individuals, although they can be experimentally induced. Under usual circumstances, therefore, neither meal initiation nor meal termination is likely to occur as a response to fluctuations of metabolic fuels. Rather, meal initiation is based on idiosyncratic factors (such as habit and convenience) and meal termination is based, at least in part, on gastrointestinal peptides secreted during the ingestion of food, as discussed below.

Meal Termination

As ingested food interacts with receptors in the gastrointestinal tract, it elicits the secretion of enzymes and generates neural and hormonal signals that help orchestrate the digestive process and customize it to the contents of the meal that is being consumed. In the early 1970s, Gibbs and colleagues provided the first solid evidence that some of these same signals originating in the gut additionally provide information to the brain that helps determine when the meal will end.⁴⁶ Specifically, they found that when the gut peptide cholecystokinin (CCK) is administered to animals prior to a meal, the animals eat less food, with larger doses of CCK causing greater suppression of meal size. This basic phenomenon has been replicated in dozens of labs using many species (including humans),^{47,48} and it can be elicited by doses of CCK that do not cause signs of illness or malaise in animals or humans.^{47,48} After receiving CCK, humans report that they stop eating sooner because they feel full.

As potent and selective agonists and antagonists to CCK receptors became available, two important new findings emerged. The first is that CCK acts uniquely at the CCK-A receptor to reduce meal size.^{49–51} Consistent with this, when antagonists to the CCK-A receptor are administered prior to a meal, individuals eat larger meals.^{49,50} This key observation implies that endogenous CCK normally contributes to the termination of meals, and it further suggests that when exogenous CCK is administered, it combines with endogenously secreted CCK to terminate the meal prematurely. The second finding is that CCK combines with other factors that limit meal size, such as gastric distension, in a synergistic manner. Hence the ability of a small dose of exogenous CCK to reduce meal size is greatly enhanced when the stomach is slightly distended.^{52,53} This observation is presumably related to the fact that

many individual sensory nerve fibers passing from the stomach and intestine to the central nervous system express more than one kind of sensory ending.⁵⁴ The possibility that one branch of a sensory neuron is sensitive to molecules such as CCK, whereas another branch of the same neuron is sensitive to stomach distension, can thus be considered. There is in fact evidence that isolated sensory axons integrate information from both CCK and gastric distension,^{52,53} and that the integrity of these axons (that travel in the vagus nerve) is essential for the ability of exogenous CCK to reduce meal size.^{55,56}

CCK is but one of several peptides secreted from the gut during a meal that reduces meal size. Others include members of the bombesin family of peptides (bombesin, gastrin-related peptide [GRP], and neuromedin-B),^{48,57} glucagon,⁵⁸ somatostatin,⁵⁹ enterostatin,^{60,61} and apolipoprotein A-IV.^{62,63} For many of these, administration of the appropriate antagonists or antibodies causes increased meal size, implying that these peptides contribute to the termination of normal meals (see reference 64). This is important because humans (as well as rats, the species in which meal size has been most extensively investigated) are general omnivores and will eat a broad spectrum of foods. The specific cocktail of peptides secreted from the gut that helps mediate the digestion and absorption of each meal can vary considerably since the various peptides are differentially responsive to different mixes or amounts of specific macro- and micronutrients. Signals comprised of combinations of peptides that gradually accumulate and stop the meal would be especially functional for omnivores. Accordingly, combinations of CCK and bombesin,⁶⁵ and of CCK and glucagon,⁶⁶ have been reported to interact to reduce meal size in rats.

In addition to those peptides secreted by the gut during meals that help to determine when meals end, the pancreatic hormone amylin (also known as islet amyloid polypeptide [IAPP]) also serves this function. Amylin is cosecreted with insulin in response to glucose and other nutrients, and, like insulin, its levels in the blood are directly proportional to body fat content.^{67–69} Also like insulin, amylin is rapidly and efficiently transported through the blood-brain barrier into the brain,^{70,71} where it interacts with receptors in the hypothalamus and area postrema of the brain stem.^{72–74} In the periphery, amylin is a potent inhibitor of gastric emptying.⁷⁵ The systemic administration of exogenous amylin causes a dose-dependent decrease of food intake and body weight,^{76–79} and amylin-deficient knockout mice weigh more than wild-type controls.⁸⁰ When administered directly into the brain, amylin decreases food intake and body weight at doses far lower than are required when it is given systemically. These data are consistent with the hypothesis that amylin has a central site of action.⁸¹ Like both insulin and leptin, amylin reduces food intake without making animals ill,^{82,83} and the central administration of insulin plus amylin causes a synergistic reduction of food intake.⁸⁴ Therefore, both intestinal (e.g., CCK and others) and pancreatic (e.g., amylin) are secreted during meals and contribute to satiety. Presumably all of these signals relay information to the brain that is related to the caloric content and make-up of food presented to the intestines during a meal. Importantly, low levels of amylin and CCK combine synergistically to reduce meal size,⁸⁵ suggesting that all of these meal-related signals interact in controlling food intake and the subjective sensation of feeling full after a meal.

In summary, evidence suggests that under normal circumstances, the physiological controls over meals are directed mainly at meal offset rather than onset. Individuals are therefore able to

adapt to a wide range of environments and consequently to accommodate imposed constraints as to when meals will occur. Ingestion of sufficient nutrients, and maintenance of appropriate levels of stored fat, is assured via regulation of how much is consumed once a meal begins. Several gut peptides secreted during the digestion and absorption of meals function as signals to the brain and act to limit meal size.

EATING AND THE REGULATION OF BODY WEIGHT

A strong interrelationship exists between body fat stores (adiposity) and food intake. All things being equal, consuming more than sufficient calories to maintain weight each day leads to increased stored energy and vice versa. Forced or voluntary overeating for several days elicits weight gain as inevitably as dieting or food restriction elicits weight loss (Fig. 10-1). In this light, body weight (mainly body adiposity) can be considered to be at the mercy of food intake. The other side of the same coin, however, is equally relevant to understanding the relationship between food intake and body fuel stores. For example, when an otherwise weight-stable adult eats insufficient food for a period of time and consequently loses weight, he or she will likely overeat when ample food once again becomes available (or when the enthusiasm for dieting wanes). Likewise, if an individual consumes excess calories to the point of weight gain for a prolonged interval, there will be an increasing tendency to eat less food and thus help return body weight and body fat stores to their preintervention levels. Viewed in this light, food intake would seem to be controlled by the amount of stored body fat. There are many reviews of these phenomena.^{10,86-90} Understanding the causal factors that interrelate food intake and body adiposity is an important goal and the subject of considerable ongoing research.

The link between body fat and food intake was formalized a half century ago when Kennedy postulated that signals propor-

tional to body fat influence the control of appetite and feeding by the brain.⁹¹ Thus Kennedy's lipostatic hypothesis stated that adiposity is regulated by a negative feedback system in which food intake is controlled in part by the amount of total stored body fat. While the existence of a link between energy intake and body energy stores has never been questioned, an important issue over the intervening years has been the nature of the signal or signals that indicate how much fat is present in the body. Because body fat is located in multiple storage depots dispersed widely throughout the body, several possibilities exist by which body fat might be monitored by the brain. For example, sensory nerves could innervate and hence provide information from each fat depot, with the accumulated information from multiple sites integrated within the brain into a reliable "total adiposity" signal. Although this is plausible in principle, adipose tissue is only sparsely innervated, and the majority of the fibers innervating fat depots are motor, controlling the release of stored energy when it is acutely needed. A second possibility is that a single fat depot is sufficiently representative of all of the others that it serves as a bellwether of sorts. In this schema, the brain need only receive a signal from this sentinel depot. Such a depot could theoretically be located anywhere, including within the brain itself. Pursuing this possibility, Nicolaidis and his colleagues have hypothesized that specialized cells within the hypothalamus serve this function and are ideally situated to influence all aspects of energy homeostasis.^{38,39} Unlike other brain cells, this "adipose-tissue homunculus" is postulated to function analogously to peripheral adipocytes and therefore to be sensitive to insulin. In point of fact, cells in the ventral hypothalamus have been found to be insulin-sensitive in that their electrical activity varies with the local application of insulin and other metabolic signals.^{17,92} More recently, neurons specifically sensitive to intracellular levels of malonyl CoA as a metabolic signal have been proposed. Malonyl CoA is a precursor for fatty-acid synthesis and its levels increase following inhibition of the enzyme fatty-acid synthase. Consistent with this hypothesis, fatty-acid synthase inhibitors potently reduce food intake, apparently via a mechanism whereby brain levels of malonyl CoA are increased.⁹³ There is also evidence for an energy homunculus being located in the liver (or at least within the influence of the hepatic branches of the vagus nerves).^{28,94} While there seems little doubt that signals related both to stored energy and to ongoing energy utilization can arise in both the brain and the liver (and presumably other tissues as well), it is not clear how much they contribute to the control of meals. Further, there is compelling evidence for a third signaling pathway, one with a strong influence on overall energy homeostasis, that utilizes hormones secreted in the periphery in proportion to the total amount of fat in the body.

FIGURE 10-1. Weight-matched rats were divided into three groups. Overfed and restricted rats received three meals per day by gavage to achieve body weights that were significantly above or below, respectively, those of ad lib-fed controls. After 140 days, the gavage feeding was discontinued and all three groups had ad lib food. The formerly overfed rats stopped eating for several days, whereas the formerly restricted rats became hyperphagic. Within 2 weeks, the weights of all 3 groups had converged and were not statistically different from one another. This is an example of long-term regulation of body weight. (Redrawn from Bernstein et al.²⁰⁴)

Circulating Adiposity Signals

When two experimental animals are joined surgically at the flank such that a small proportion of the circulation exchanges between them (termed parabiotic animals), the existence of circulating adiposity signals is revealed. In a typical such experiment, two otherwise normal animals with similar body weight (either two lean or two obese rats or mice) are parabiotically joined. In this situation, each animal eats normally and maintains its customary (presurgical) body weight. These control experiments indicate that the parabiotic procedure itself is tolerated and that both normal-weight and obese animals can still maintain their body weight. Contrary to this, when an obese animal is parabiotically joined with a lean part-

ner, their respective body weights diverge rather than converging. The obese partner often gains a little weight, but the dramatic effect occurs with the lean partner, which may stop eating all together and which loses body weight precipitously.⁹⁵ Unless the two partners are separated, the lean animal might starve itself to death. Such experiments have been interpreted to indicate that a circulating signal proportional to body fat passes between the two parabiotic partners. The relatively high titer of the signal entering the lean animal from its obese partner is hypothesized to provide a false message that too much fat exists in the lean animal's body. The lean animal consequently responds to this increased signal by reducing its food intake and losing weight. Hence a circulating signal can have a powerful influence over eating behavior, and an important implication of this is that the administration of the exogenous signal can effectively elicit weight loss.

The best candidates for circulating indicators of body fat are several peptide hormones that are secreted from peripheral organs in proportion to body adiposity and that are transported into the brain from the circulation. The two most investigated are leptin, which is secreted from adipose tissue, and insulin, which is secreted from the β cells of the pancreas. Both are synthesized and secreted in direct proportion to the amount of fat in the body. In the section below, we review the evidence that each of these peptides satisfies criteria for being an adiposity signal to the brain.

Insulin as an Adiposity Signal

To be considered an adiposity signal, a compound should be secreted in proportion to body fat, should have access to appropriate areas of the nervous system, and should influence food intake and body weight in predictable ways.^{11,90,96,97} Insulin was the first hormone proven to have these properties (see reviews in references 98 and 99). Insulin is, of course, the body's predominant controller of blood glucose, and its secretion from the pancreas is controlled in large part by ambient glucose. Nonetheless, the responsiveness of the β cells to glucose (and to most other secretagogues as well) is proportional to body fat.¹⁰⁰⁻¹⁰² A fatter individual has higher basal insulin and secretes proportionally more insulin to a given increase of blood glucose than does a lean individual. Hence, plasma insulin reflects both acute metabolic needs as well as body fat content. Circulating insulin gains direct access to areas of the brain with a reduced blood-brain barrier (such as the circumventricular organs). Perhaps more importantly, brain capillary endothelial cells contain insulin receptors, and insulin penetrates into the brain from the blood via a receptor-mediated, intracellular transport process (see reviews in references 99, 103, and 104). Hence, circulating insulin has access to neurons and glial cells throughout the brain.

Insulin receptors are expressed in brain regions important in the control of energy homeostasis such as the ventral hypothalamus.¹⁰⁵⁻¹⁰⁸ Insulin receptors are also expressed in other brain regions (e.g., the olfactory bulbs and the hippocampus) where their function is less well understood. Within the hypothalamus, the arcuate nuclei (ARC) have particularly high densities of insulin receptors, and the ARC is the location of at least two major types of neurons that potentially influence food intake (see below). Hence these cells have the capacity to detect and respond to insulin and are therefore also indirectly sensitive to body adiposity.

When exogenous insulin is administered directly into the brain (into the ARC itself, into nearby ventral hypothalamus, or into the cerebrospinal fluid in the adjacent third ventricle), animals behave as if they are overweight (i.e., they eat less food and lose weight)

FIGURE 10-2. Weight-matched rats were divided into four groups, two being food restricted for days 1 through 3 and the other two having ad lib food. All four groups had ad lib food after day 3. One of the restricted groups and one of the ad lib-fed groups received insulin (10 mU/d) infusion into the third cerebral ventricle throughout via osmotic minipumps (INS/FD; INS/AD LIB); the other restricted and ad lib-fed groups received a third ventricular infusion of physiological saline (VEH/FD; VEH/AD LIB). The ad lib-fed rats receiving saline gained weight over the 10 days of the experiment, whereas the ad lib-fed rats receiving insulin ate less food and lost weight. Both restricted groups lost weight over the 3 days without food, and those getting insulin lost significantly more weight after 1 and 2 days. When food was returned at the end of the third day, both groups were significantly hyperphagic. However, the formerly restricted rats getting insulin ate only enough to reach the same body weight plateau as the other insulin group, whereas the formerly restricted rats receiving saline gained more weight and were approaching the weight of the other saline group by the end of the experiment. Hence rats receiving insulin into the brain ended up at a lower body weight than saline-infused controls, and they achieved the same absolute weights whether they had to eat less (nonrestricted group) or more (restricted group) to achieve it. (Reproduced from Chavez et al.¹²⁴)

(Fig. 10-2).¹⁰⁹⁻¹¹⁴ This response develops over several hours and is proportional to the amount of insulin administered. Conversely, when local concentrations of insulin are reduced (by administering antibodies to insulin into the brain), animals eat more food¹¹⁵ and gain weight.¹¹⁶ Consistent with these observations, mice with targeted deletion of the insulin receptor in neuronal tissue have enhanced food intake and body weight gain, particularly on a high-fat diet.¹¹⁷ Recent data suggest that insulin's neuronal effects involve downstream molecules such as the product of the *tubby* gene (Tub) and IRS-2 since activation of insulin receptors phosphorylates these proteins, and since mice with genetic alterations of these proteins have obese phenotypes.^{118,119}

These findings support the hypothesis that insulin is an adiposity signal to the brain. A key prediction of this hypothesis is that an experimentally-induced elevation of plasma insulin should result in a decrease of food intake since brain insulin would be anticipated to increase secondarily and proportionally to the increment in the blood. This has been difficult to investigate in a simple way, because when plasma insulin is experimentally increased, it causes a rapid decrease in blood glucose (and frank hypoglycemia), which itself causes animals to eat more food.^{22,23,30} This scenario of an increase of plasma insulin in the absence of an *a priori* increase of plasma glucose would not normally occur. Rather, elevations of endogenous insulin typically occur in response to already elevated blood glucose, and function to reduce glucose to normal levels as

opposed to eliciting hypoglycemia. When circulating insulin is experimentally elevated and hypoglycemia is circumvented, animals eat less food.^{120–122} Conversely, conditions associated with low circulating insulin (e.g., fasting and uncontrolled T1DM) are associated with hyperphagia. These observations support the hypothesis that insulin's effects in the brain and in peripheral tissues oppose one another where energy homeostasis is concerned. Thus, whereas systemically-acting insulin promotes fat deposition, centrally-acting insulin functions as an adiposity signal that limits weight gain. Moreover, insulin-induced weight loss is not due to toxic or aversive effects, since when it is administered into the brain at doses that reduce food intake and body weight, the animals are neither ill nor incapacitated. Rather, they act as if they are maintaining and defending a lower body weight.^{123,124} This collective evidence implicates insulin as an adiposity signal to the brain.

Leptin as an Adiposity Signal

Although its existence was inferred from experiments done over 25 years ago on parabiotic mice,¹²⁵ leptin was not discovered and described until 1994.¹²⁶ Leptin is secreted from adipocytes in direct proportion to the amount of stored fat^{127,128} via a mechanism that is sensitive to ongoing metabolic activity of fat cells, in addition to fat content *per se*.^{129,130} Hence dissociations can occur between stored fat and leptin release, particularly when there is a rapid decrease of adipocyte glucose metabolism such as occurs in fasting.^{131–133} In such instances, plasma leptin decreases more rapidly and to a greater degree than does body fat, but among individuals in neutral energy balance, plasma leptin levels are a reliable indicator of body fat content. As is the case with insulin, circulating leptin is transported through the blood-brain barrier into the brain,^{134–138} and leptin receptors are located within the ARC and other nuclei in the ventral hypothalamus (among several other regions).^{139,140} Systemic administration of leptin decreases food intake and body weight in rodent models^{141–143} and in leptin-deficient humans.¹⁴⁴ The finding that the dose needed to reduce food intake is much lower when leptin is administered into the brain ventricles than into systemic circulation^{141,143} implicates the brain as a key target of leptin action (Fig. 10-3). Moreover,

FIGURE 10-3. Rats were administered leptin (3.5 μ g) or its vehicle, physiological saline, into the third cerebral ventricle on two separate days. The order of receiving the two substances was random for each rat. When the rats received leptin, food intake was significantly reduced. (Redrawn from Seeley et al.¹⁴³)

anorexia induced by leptin is dose dependent and is not secondary to illness or incapacitation.¹⁴⁵ Animals with defective leptin signaling (either because they do not synthesize leptin, as in *ob/ob* "obese" mice, or because they have defective leptin receptors, as occurs in *db/db* "diabetic" mice and *fafa* "fatty" Zucker rats) are characterized by hyperphagia and extreme obesity, and the same is true for humans with analogous mutations of leptin and its receptor.¹⁴⁶ Hence leptin, like insulin, satisfies the criteria for being an adiposity signal to the brain.

Insulin is secreted in response to minute-to-minute changes in circulating fuels and autonomic activity, and it has a half-life of a few minutes. Thus the rapidly fluctuating titers of insulin reaching the brain reflect instantaneous metabolic needs as well as total body fat. Leptin, on the other hand, has a much longer half-life (around 45 minutes) and therefore provides a more stable signal to the brain regarding body fat stores. Insulin secretion is more highly correlated with visceral fat than with total body fat, and visceral fat is highly associated with insulin resistance. Leptin on the other hand is more highly correlated with subcutaneous than visceral fat. The integration of these different types of signals with central controllers of energy homeostasis is the subject of considerable ongoing research.

CENTRAL CONTROL SYSTEMS

Signals proportional to body adiposity, as well as those that communicate information related to ongoing metabolic processes and what is being eaten and processed in the gut, converge in the central nervous system (CNS). Within the CNS, these signals act on neurochemical systems that influence energy intake and energy expenditure. The best-described CNS systems that regulate energy homeostasis are in the ventral hypothalamus, and they can be roughly divided into those whose activity reduces body fat (catabolic effector systems) and those whose activity increases body fat (anabolic effector systems).^{11,97,147} Anabolic effectors are neuronal circuits that elicit increased food intake, decreased energy expenditure and, consequently, increase stored energy in the form of adipose tissue. They become more active when energy stores are low, as indicated by reduced levels of insulin and leptin (i.e., when the body is in negative energy balance). Catabolic effectors are neuronal pathways that do the opposite. Stimulated during times of positive energy balance, they decrease food intake, increase energy expenditure, and result in decreased adiposity. A critical aspect of this negative feedback system is that adiposity signals appear to inhibit anabolic pathways while activating catabolic pathways, and the balance between these two pathways is thought to strongly influence the individual's feeding behavior in response to changes in the level of adiposity.^{90,97}

The catabolic and anabolic effector systems are comprised of a number of discrete neurotransmitter systems and axonal pathways within the brain, and many important details of this control system have emerged in recent years. Although receptors for leptin and insulin and binding sites for amylin are located throughout the CNS, all three are concentrated in the ARC in the ventral hypothalamus. Hence, ARC neurons are sensitive to these hormones and consequently to the degree of body adiposity.

Anabolic Effector Systems

The most investigated anabolic effector transmitter is neuropeptide Y (NPY). Although NPY mRNA is made widely throughout the brain, NPY-synthesizing cell bodies in the ARC are implicated as

being particularly important in the control of energy homeostasis. Among the many NPYergic projections from these neurons, those to the nearby paraventricular nuclei (PVN) of the hypothalamus and the lateral hypothalamic area (LHA), appear to be major controllers of food intake. ARC NPYergic neurons respond to negative energy balance (i.e., to food deprivation or starvation) by synthesizing more NPY mRNA, and more NPY is consequently released in the PVN^{148–150} and presumably the LHA as well. This response is proposed to contribute to increased feeding behavior when food becomes available. Activation of hypothalamic NPY signaling in states of negative energy balance appears to be triggered by reduced levels of adiposity hormones, and the local replacement of either insulin or leptin in the vicinity of the ARC in such individuals attenuates the elevated NPY mRNA in the ARC.^{150,151} Hence, the activity of these ARC NPY neurons is directly influenced by at least these two adiposity signals.

Consistent with its proposed role as an anabolic effector peptide, administration of exogenous NPY into the PVN or into the adjacent third cerebral ventricle elicits a rapid and robust increase in food intake^{152–156} and decrease of energy expenditure in animals.^{157,158} Repeated daily administration of NPY elicits sustained increases of food intake, body weight, and body adiposity,¹⁵⁵ and local administration into the ARC of antisense oligonucleotides to NPY results in reduced NPY synthesis in the ARC and reduced food intake and body weight.¹⁵⁹ Thus NPY satisfies the criteria for being an anabolic effector peptide. Controversy regarding the exact role of NPY stems from experiments on mice with targeted deletion of the NPY gene. These animals do not have differences in food intake or body weight compared to wild-type controls,¹⁶⁰ demonstrating that NPY is not required for normal levels of food intake and body adiposity to be maintained. However, when NPY-deficient mice are crossed with *ob/ob* mice, the hyperphagia and obesity induced by leptin deficiency are partially (but not fully) reversed. Consequently, it would appear that while elevated NPY signaling is an important part of the phenotype of *ob/ob* mice, there must also be other mediators of the response to leptin deficiency.¹⁶¹

Hypothalamic Catabolic Effector Systems

At least one catabolic system with effects on energy balance opposite to those of the ARC NPY system also originates within cell bodies in the ARC. Considerable evidence implicates the hypothalamic melanocortin system as an important catabolic effector system. Melanocortins are a family of peptides that includes ACTH and α -melanocyte-stimulating hormone (α -MSH), derived from the precursor molecule proopiomelanocortin (POMC). In the mammalian forebrain, POMC is synthesized only in ARC neurons that are distinct from, but adjacent to, those that synthesize NPY.¹⁶² One of the neuropeptides cleaved from ARC POMC is α -MSH, a peptide transmitter that is an agonist at hypothalamic melanocortin receptors that are concentrated in areas such as the PVN and LHA. When administered into the third ventricle, α -MSH and other melanocortin receptor agonists (including the synthetic drug MTII) reduce food intake and body weight, whereas administration of synthetic melanocortin receptor antagonists (such as SHU-9119) increases food intake and body weight.^{163–166} POMC gene expression is reduced during negative energy balance¹⁶⁷ and increased during positive energy balance.¹⁶⁸ Consistent with the hypothesis that the melanocortin system is important in mediating the effects of leptin, leptin receptors are found on POMC neurons in the ARC,¹⁶⁹ leptin stimulates ARC POMC gene expression,¹⁶⁷ and administration of a melanocortin receptor antagonist blocks the effect of leptin to reduce food intake.¹⁶⁴ All of this evidence points to the

hypothalamic POMC- α -MSH-melanocortin receptor system as being a key catabolic effector pathway capable of eliciting robust effects on food intake and body weight that mediates some of the effects of adiposity signals in the CNS. Moreover, it suggests strongly that normal energy homeostasis is dependent on intact melanocortin signaling.

Two melanocortin receptors, termed MC3 and MC4, have been identified within the hypothalamus.¹⁷⁰ Of these, the stronger case can be made for MC4 receptors being involved in the control of energy homeostasis. When administered into the third ventricle of the rat, selective MC4 receptor agonists inhibit and selective MC4 antagonists stimulate food intake.¹⁷¹ A critical role for MC4 receptor signaling in weight regulation is suggested by the phenotype of MC4 knockout mice. These animals have increased food intake and frank obesity, and they are insensitive to the actions of nonselective MC4 receptor agonists to reduce food intake.¹⁷² MC3 receptor-deficient mice also have increased body fat, but the effect is small and is not driven by increased food intake.¹⁷³

Complexities of the Arcuate Nucleus System

An important interaction that functionally links NPY and POMC neurons in the ARC was recently discovered. Surprisingly, NPY-synthesizing neurons in the ARC make and secrete a second anabolic neuropeptide, agouti-related peptide (AgRP).^{174–176} an endogenous antagonist of CNS MC3 and MC4 receptors.¹⁷⁵ Parallel to what occurs following the administration of exogenous NPY, administration of AgRP potently stimulates food intake and body weight gain.^{168,177,178} Thus the same ARC neurons release two different orexigenic neuropeptides from their axon terminals. NPY acts at NPY receptors (Y1 and Y5 receptor subtypes) to create an anabolic effect, whereas AgRP acts at MC4 receptors to inhibit α -MSH-mediated catabolic effects (Fig. 10-4). NPY/AgRP neurons of the ARC thereby promote a positive energy balance and weight gain via distinct but complementary mechanisms.

Other Hypothalamic Systems

The model discussed here places ARC anabolic and catabolic neurons at the hub of the system by which input from adiposity signals is transduced into behavioral and autonomic responses. The subsequent downstream neuronal events that control energy homeostasis are complex and diverse. However, as indicated above, two important areas are the nearby PVN and LHA. Each of these pairs of hypothalamic nuclei receives rich inputs from both NPY/AgRP and POMC neurons in the ARC,^{179,180} and each synthesizes several neuropeptides that are important in the energy balance equation. The PVN, for example, contains neurons that synthesize corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), and oxytocin, and the central administration of any of these has a net catabolic effect.^{90,97} Since ablation of the PVN causes a chronic anabolic condition characterized by hyperphagia and obesity (see reference 181), a rough generalization is that the PVN is a key component of the catabolic effector system. Analogously, the LHA, the other major recipient of axons from the ARC, synthesizes melanocyte-concentrating hormone (MCH)¹⁸² and the orexins.^{183,184} These neuropeptides, when administered into the CNS, cause a net anabolic response. Thus regulation of activity of ARC neurons by input from adiposity signals may alter feeding behavior in part via changes in the output of catabolic second-order neurons in the PVN and anabolic second-order neurons in the LHA. However, leptin and insulin receptors are present in the PVN and other

FIGURE 10-4. Model of the initial steps in the hypothalamic control of body fat content. Leptin and insulin are secreted and circulate in direct proportion to body fat. Leptin directly from white fat and insulin in direct proportion to white fat. They pass through the blood-brain barrier and interact with two types of cells in the hypothalamic arcuate nucleus. Leptin and insulin inhibit activity in cells that synthesize neuropeptide Y (NPY) and agouti-related peptide (AgRP), and they enhance activity in cells that synthesize proopiomelanocortin (POMC). NPY interacts with Y1 and/or Y5 receptors on neurons in other hypothalamic areas, causing a net anabolic effect by stimulating food intake and decreasing energy expenditure. The peptidergic neurotransmitter cleaved from POMC, α -melanocyte-stimulating hormone (α -MSH), interacts with MC4 receptors on neurons in other hypothalamic areas, causing a net catabolic effect by decreasing food intake and increasing energy expenditure. AgRP is an antagonist at those same MC4 receptors, such that AgRP opposes the actions of α -MSH.

areas, so some neuronal responses to input from these hormones are likely to be independent of the ARC. Moreover, LHA neuronal systems project dense fiber networks to the ARC that may have important effects on the output of NPY/AgRP and POMC neurons. A highly integrated and redundant neurobiological system is thus likely to mediate feeding responses to a change of energy balance.

Interaction of Adiposity Signals with Signals That Control Meal Size

A key question concerns how the various control systems described in this chapter are integrated in the control of food intake. That is, what are the interrelationships among the systems that signal ingested calories and control meal size, those that signal adiposity, and those hypothalamic neuropeptides and other neurotransmitters that receive feeding-pertinent inputs from throughout the brain? Although precise answers are not yet at hand, a model is emerging that is consistent with most of the data, and it is summarized in Fig. 10-5.

When rats have free access to food and can eat whenever they choose, they generally eat 10–12 meals a day, with most intake occurring during the night.^{185,186} West and associates observed that when CCK was administered to free-feeding rats at the onset of each meal via an automated delivery system over a 1-week period, the size of each meal was reduced.¹⁸⁷ However, the rats maintained essentially normal total daily caloric intake and body weight, since they increased the number of times they initiated meals each day. This suggests that administration of exogenous CCK alone is an ineffective treatment for losing weight. Nonetheless, rats with a chromosomal deletion that mutates CCK-A receptors¹⁸⁸ gradually become obese over their lifetime,¹⁸⁹ suggesting that an inability to terminate meals appropriately may contribute to a gradual expansion of body fat.¹⁹⁰ Moreover, CCK and adiposity hormones such

as insulin or leptin have additive, or even synergistic effects, to reduce food intake. For example, rats treated with very low, sub-threshold doses of either exogenous insulin or leptin manifest a marked increase in the hypophagic response to a low dose of CCK given once a day,^{191–194} and they lose weight beyond that achieved by giving these peptides by themselves.^{195,196} This observation suggests that the efficacy of CCK (and presumably other signals that reduce meal size as well, such as amylin⁸⁴) is enhanced in the presence of elevated adiposity signaling in the brain. The infusion of a low dose of leptin directly into the brain also increases the sensitivity of the vagus nerve to gastric distension signals that reduce meal size,¹⁹⁷ and leptin-induced anorexia is, in fact, characterized by consumption of smaller meals with no change of meal frequency.¹⁹⁸ The effect of increased adiposity signaling to reduce energy intake may therefore depend largely on an increased response to signals that terminate meals.

These observations have important implications. When an individual goes on a diet and starts losing weight, there is a concomitant reduction of the secretion of adiposity signals (leptin and insulin) and lower titers of these signals enter the brain. In fact, an acute fast, in and of itself, is sufficient to reduce the transport of insulin¹⁹⁹ or leptin¹³⁷ into the brain. One consequence of reduced adiposity signaling is a reduced ability of meal-generated peptides such as CCK to terminate a meal, with the result that meals will tend to be larger until adiposity signaling (and body weight) are normalized. Likewise, an individual who overeats and gains weight will have increased adiposity signaling in the brain and will consequently tend to eat smaller meals, providing that they remain sensitive to adiposity signals. Hence, the net action of this control system is to counter long-term changes in body weight, and it does so by changing the average size of meals. Note that individuals are still able to eat according to whatever schedule best meets their

FIGURE 10-5. Model depicting the multiple levels of input and control of energy homeostasis. Body fat content is signaled to the brain via leptin and insulin acting in the hypothalamus. Signals pertinent to food being eaten arise within the gastrointestinal system and reach the brain through sensory nerves converging in the brain stem. The hypothalamic and brain stem areas integrate this information with other factors to determine food intake and energy expenditure.

lifestyle and environmental constraints; it is the meal size rather than the meal pattern that is controlled by this regulatory system.

An important unanswered question relates to what happens to this control system when the diet is changed. A strong case can be made that when individuals habitually consume diets rich in fat, they tend to become obese.^{1,4,200–202} This indicates that the normal feedback signaling system must become altered or insensitive on a high-fat diet, and biochemical evidence of leptin resistance in the hypothalamus is beginning to emerge in animals placed on high-fat diets.²⁰³ As the prevalence and associated morbidity of obesity continue to increase in modern society, the importance of understanding the interactions between diet and other environmental factors with the weight-regulatory system increases in parallel. Progress in the prevention and treatment of obesity will likely emerge from an improved understanding of these interactions.

Diabetes and Atherosclerosis

Daniel Steinberg

Diabetic patients frequently suffer from microvascular disease, but they die more commonly from macrovascular disease. Atherosclerosis affecting the cerebral arteries and the peripheral vasculature takes a toll, but myocardial infarction certainly leads as cause of death. Physicians caring for diabetic patients must be as concerned about the other risk factors for coronary artery disease as they are about the control of glycemia in their patients. Certainly the diabetic patient in poor metabolic control manifests significant derangements of lipoprotein metabolism and this deserves attention. However, diabetic patients who are well controlled do not have significant hypercholesterolemia and only minimal hypertriglyceridemia. Yet they are at significantly higher risk for premature coronary heart disease (CHD). Why? Perhaps due to low high-density lipoprotein (HDL) levels or hypertriglyceridemia. But the blunt answer is that we simply do not know. (The disturbances in lipid metabolism and lipoprotein patterns encountered in diabetes are discussed in detail in Chap. 47). However, there is reason to believe that every effort should be made to correct the acknowledged risk factors for CHD in diabetic patients just as in nondiabetic persons—but even more aggressively, because they are at higher risk. Most of the risk factors, including dyslipidemia, cigarette smoking, hypertension, and obesity, have been shown to apply equally in the presence of diabetes mellitus and, in general, they can be treated in the same ways. Moreover, clinical intervention trials have now shown that diabetic subjects benefit at least as much from lipid-lowering therapy as do nondiabetics.¹⁻³

This chapter summarizes recent advances in the understanding of the pathogenesis of atherosclerosis. Over the last two decades a great deal has been learned about the cellular and molecular events in the artery wall that lead to the initiation and progression of lesions. Advances in cell biology and molecular biology have led to the elucidation of a generally agreed-upon sequence of events for lesion initiation in the artery wall and the identification of a number of growth factors and cytokines that influence those events. Particular interest is focused on the role of oxidative modification of LDL in atherogenesis, and some evidence is available to suggest that oxidation of LDL may proceed at a higher rate in diabetic animals. The purpose of this chapter is to briefly review current understanding of atherogenesis and to point out some of the ways that diabetes mellitus may accelerate the process.

CURRENT CONCEPTS OF ATHEROGENESIS

It is probably a mistake to think of atherosclerosis as a single, well-defined disease entity. It is more likely that it has multiple causes

and that the weight of each potential cause varies from individual to individual and possibly even from lesion to lesion. The best established risk factor—and the one most clearly demonstrated to act directly on the vessel wall—is hyperlipoproteinemia. The strikingly low incidence of CHD morbidity and mortality in the Japanese population, where total cholesterol levels have in the past averaged about 165 mg/dL, speaks volumes about the importance of hypercholesterolemia as a risk factor.⁴ This is not reflective of a genetic resistance to cholesterol-induced atherosclerosis, because the Japanese who migrate and adopt Western diets in Honolulu or San Francisco acquire higher cholesterol levels and with them a higher incidence of coronary artery disease.⁵ The low incidence in Japan is especially remarkable because smoking and hypertension, the two most important additional risk factors, are so prevalent in that population.

There is now general acceptance that an elevated low-density lipoprotein (LDL) or a low HDL level constitutes an important determinant of atherosclerosis, and national programs are in place to deal with dyslipidemia. Many studies have now demonstrated that correction of hypercholesterolemia reduces the rate of progression of atherosclerosis and reduces the incidence of CHD morbidity and mortality.^{1-3,6} Only recently, however, have we begun to understand the mechanisms by which a high LDL level in the plasma influences the initiation and progression of the arterial lesion. In the following sections an outline of the current consensus regarding the processes in the artery wall triggered by hypercholesterolemia is presented. A discussion follows of how diabetes mellitus may intersect with and influence the rate at which these processes occur. An overall schema is presented in Fig. 11-1.

Initiation: The Fatty Streak

The fatty streak is the earliest grossly detectable lesion of atherosclerosis. It is a very slightly elevated, yellowish lesion made up predominantly of lipid-laden foam cells. Most of these are derived from circulating monocytes; a smaller number are derived from smooth muscle cells (SMCs). The endothelial lining overlying a fatty streak is intact. The view that loss of endothelial cells might be a necessary first step in the initiation of atherogenesis has been largely discounted. Many carefully conducted studies show no loss of endothelial cells *until later in the course of the disease*. However, the loss of endothelial cells may signal the transition from the first phase of atherosclerosis to the second phase. Thus, the monocyte-derived foam cells represent mostly circulating monocytes that have penetrated between endothelial cells, entered the

ATHEROSCLEROSIS INDUCED BY HYPERCHOLESTEROLEMIA

FIGURE 11-1. Schematic summary of the unit processes in the aortic wall contributing to atherogenesis. (Reprinted with permission from Steinberg et al.³³)

intima, and taken up lipoproteins with the consequent storage of cholesterol esters in multiple droplets.

One of the earliest observable responses in animals fed a cholesterol-rich diet is an increase in the adherence of circulating monocytes to the arterial endothelium. This was first emphasized by Gerrity⁷ and confirmed many times over. Hypercholesterolemia in some way induces the expression of specific adhesion molecules on the endothelial cells, one of which is vascular cell adhesion molecule-1 (VCAM-1) as shown by Li and colleagues.⁸ Hypercholesterolemia may also influence the behavior of the circulating monocyte by increasing the probability of its adhesion to endothelium. A large body of literature is developing regarding the selectins and integrins involved in cell-cell interactions, and it seems likely that many additional adhesion molecules will be defined as research progresses. The monocytes that adhere then penetrate in response to chemotactic factors, some of which have been identified. Oxidatively modified LDL can act directly as a chemoattractant.⁹ It can also act indirectly by stimulating release of monocyte chemoattractant protein-1 (MCP-1) from endothelial cells.¹⁰ The central importance of monocyte chemoattractant protein 1 (MCP-1) and its receptor on the monocyte CCR2 (CC chemokine receptor 2) has been established by gene targeting. Knocking out either gene in a mouse model of atherosclerosis slows lesion progression by 50–80%.^{11,12} Platelet-derived growth factor (PDGF) produced by endothelial cells, macrophages, and SMCs is another candidate chemoattractant.

Once in the subendothelial space, the monocyte undergoes a differentiation process that radically alters the repertoire of genes

expressed and the cell acquires the properties of an arterial tissue macrophage. Exactly how this differentiation is accomplished remains uncertain, but it is known that macrophage colony-stimulating factor (MCSF), produced by endothelial cells and macrophages and whose production can be enhanced by oxidized LDL,¹³ speeds this differentiation process.

The next step is the accumulation of lipids. It is known that these lipids have their origin in the plasma lipoproteins. The artery wall itself synthesizes almost no cholesterol and the lipid in the foam cells is primarily cholesterol esters. Studies in experimental animals, and some studies in humans, support the conclusion that essentially all of the cholesterol esters that accumulate are derived from circulating lipoproteins. Here a paradox is encountered. In cell culture, neither the circulating monocyte, the tissue macrophage, or the smooth muscle cell can take up native LDL fast enough to build up their cholesterol content significantly.^{14,15} This is in part because they take up native LDL by way of the Goldstein-Brown LDL receptor, a receptor that is downregulated as soon as the cholesterol content of the cell begins to increase.¹⁶ This is the normal response that prevents excessive accumulation of cholesterol that can be damaging to cells. How then do we account for the continuing build-up of cholesterol to extremely high levels in macrophages and SMCs in the wall of the artery? These cells can stuff themselves with cholesterol to the point where as much as half of the total dry weight of the cell is represented by lipid.

An even greater paradox is encountered when we consider the lesions in patients with familial hypercholesterolemia. These patients, who totally lack LDL receptors, nevertheless show foam cell

accumulation in their lesions much like patients who have normal LDL receptors and very high plasma levels of LDL. Evidently, uptake by way of the LDL receptor, a major route of lipoprotein uptake in most cells of the body, is not the mechanism by which the LDL cholesterol is delivered to these cells (or at least it need not be). These two paradoxes almost forced the conclusion that LDL must be modified in some way prior to its uptake by macrophages. Suffice it to say at this point that oxidation of LDL modifies it into a form not recognized by the native LDL receptor, but recognized by alternative receptors on the macrophage. These presumably are receptors that do not downregulate. In this modified form, LDL can be taken up rapidly enough that there is a progressive build-up of cholesterol esters in the cell.

Fibrous Plaque Formation

The earliest fatty streak lesion consists primarily of monocyte/macrophage-derived foam cells plus some smooth muscle cell-derived foam cells. From the beginning, however, one can find a few T lymphocytes as well. These do not contribute to the foam cell population, but they may play a central role in the transition of the fatty streak to a fibrous plaque. This process shares many of the features seen in chronic inflammatory processes elsewhere in the body. Every one of the major cell types involved—endothelial cells, macrophages, T lymphocytes, and SMCs—is capable of generating and releasing chemotactic factors, mitogenic factors, and cytokines of many kinds. Some are proinflammatory and others anti-inflammatory. The array of factors that *may* be involved has been reviewed extensively elsewhere.^{17,18} It is sufficient to note here that the end result is a recruitment of SMCs from the media up through a fragmented internal elastic membrane; the replication of these cells; the secretion of proteoglycans, collagen, elastin, and other connective tissue matrix elements; and the formation of a fibrous cap over the top of the lesion.

Exactly what triggers the transition from fatty streak to fibrous plaque is not certain. There are some populations in which fatty streaks are rather prevalent, but they rarely go on to become fibrous plaques or clinically significant lesions of any kind. Thus the progression is not inevitable, and it would be of great significance if the triggers were identified. One suggestion is that the endothelial cell lining overlying a fully developed fatty streak loses its integrity, exposing the underlying lesion to the bloodstream. This would allow platelet aggregation to occur, with the consequent release of many cytokines, including PDGF, that might then accelerate the progression of the fatty streak to the fibrous plaque. In a sense, this would represent a repair process.

The fibrous cap is not itself a nidus for thrombosis. The fibrous plaque can progress and eventually cause clinically significant stenosis. However, the lesion that is a serious threat is one in which the fibrous cap becomes eroded, culminating in plaque rupture and a terminal thrombosis.

Conversion of the Fibrous Plaque to the Complex Lesion: Plaque Rupture

Over many years the fibrous plaque can build up as a result of SMC replication and deposition of matrix material. There is probably always some continuing lipid accumulation at the growing edges of the lesions that continues to include many macrophages and T lymphocytes. In other words, the lesions extend at their periphery, and at their periphery they retain many of the properties of the original

fatty streak. Eventually, the lesion matures such that there is a fibrous cap and beneath it a pool of lipid. Presumably, the lipid-laden foam cells eventually become necrotic, and it seems likely that the pool in the necrotic core of lesions represents lipid that once was contained within the foam cells. Stenosis as a result of the progressive growth of the lesion can ultimately restrict blood flow to the point that patients will experience angina. They may even have infarction because of disproportion between demand and flow. More commonly, the infarction results from thrombosis that occurs when a plaque ruptures. The pioneering work of Constantinides¹⁹ and the more recent work of Davies²⁰ make this very clear. What triggers the rupture is not certain, but it could relate to activity of the macrophages at the shoulders of the lesion with release of lytic enzymes, tissue-damaging free radicals, or oxidized lipids. These could erode the thinning fibrous cap, and in concert with hemodynamic forces, bring about the rupture. That in turn exposes the blood to tissue factor and other prothrombogenic factors in the lipid pool, and triggers the potentially fatal thrombosis.

THE OXIDATIVE MODIFICATION HYPOTHESIS

We referred in the section on lesion initiation to the double paradox relating to foam cell formation. Goldstein and coworkers¹⁴ recognized the paradox and attempted to modify LDL into a form that monocytes and macrophages would take up rapidly enough to become foam cells. They demonstrated that chemical acetylation of LDL (treatment with acetic anhydride) converted it into a form that was taken up much more rapidly than native LDL. Moreover, it was taken up by a specific, saturable mechanism. They named the receptor the “acetyl LDL receptor.” The key point is that this receptor, unlike the native LDL receptor, does not downregulate as the cholesterol content of the cell increases progressively. The acetyl LDL receptor was subsequently cloned and characterized by Kodama and colleagues. They named it the “scavenger receptor.”²¹ It now appears that there are several families of scavenger receptors,²² and the acetyl LDL receptor is now referred to as a class A scavenger receptor.

The work of Goldstein and Brown on macrophage metabolism of lipoproteins was seminal,^{14,23} but there was no evidence then (and there is still none) that acetylation of LDL takes place in the body. Henriksen and associates in 1981 were the first to describe a biologically plausible modification of LDL that might account for foam cell formation.²⁴ They showed that incubation of LDL with cultured endothelial cells led to a modification, later shown to be an oxidative modification,^{25,26} that made it a ligand for specific receptors on the macrophage. A part of the uptake, which was saturable, was attributed to the acetyl LDL receptor, but as much as 40% or more could not be via that receptor, but by a different receptor or receptors.

Soon after the discovery that oxidative modification converted LDL to a ligand for specific macrophage receptors, additional biologic properties of oxidized LDL were discovered that could further enhance its atherogenicity. For example, oxidized LDL was shown to be chemotactic for monocytes⁹ and later for T lymphocytes.²⁷ It was shown that oxidized LDL *inhibited* the motility of tissue macrophages and thus might cause a trapping of these cells once they entered the subendothelial space.²⁸ Work by Morel and coworkers^{26,29} showed that oxidized LDL was cytotoxic, which certainly could contribute to its atherogenicity, particularly in the transition from the fatty streak to the fibrous plaque. Studies by

Cushing and associates¹⁰ and by Rajavashisth and coworkers¹³ showed that even very mildly oxidized LDL (minimally modified LDL; MM-LDL) has biologic properties that are proatherogenic even before the lipoprotein loses its affinity for the LDL receptor and long before it becomes a ligand for scavenger receptors. They showed that minimally oxidized LDL could stimulate the release of MCP-1 and MCSF from endothelial cells, even though the oxidized LDL used was not a ligand for the scavenger receptor. The list of biologic properties that could in principle make oxidized LDL a more atherogenic lipoprotein than native LDL has grown by leaps and bounds, and at last count there were more than 15 such properties. How many of these properties, demonstrated in cell culture systems, are quantitatively important in the atherogenic process *in vivo* remains to be ascertained. It is sufficient to say here that the conversion of LDL to its oxidized form affects both lipids and protein, and that the oxidized form is significantly more atherogenic than the native form. Consequently, any intervention that inhibits the oxidation of LDL should theoretically be able to slow the progression of atherosclerosis. Conversely, any metabolic error that increases the rate of oxidation of LDL or enhances its proatherogenic properties could speed the progression of atherosclerosis. The next section will identify metabolic abnormalities associated with diabetes that might do this. Before that, an outline of the evidence supporting the oxidative modification hypothesis and some of the uncertainties with regard to its relevance in humans are discussed.

The current status of the oxidative modification hypothesis is summarized in Table 11-1. The theoretical basis for the hypothesis is well supported by an extensive body of work at the experimental level as reviewed in references 30–33. Considerable evidence that oxidative modification does indeed occur *in vivo* has accumulated over the years and includes the following: (1) demonstration of the presence of oxidatively modified LDL in atherosclerotic lesions (but not in normal arteries) and, to a limited extent, in circulating plasma; (2) demonstration by immunohistochemical methods that epitopes of oxidized LDL are represented in lesions but again, not in normal arteries; (3) demonstration of autoantibodies in plasma, signaling the presence *in vivo* of either oxidized LDL itself or a closely related antigen; and (4) demonstration that antioxidants can significantly inhibit the rate of progression of early atherosclerosis in experimental animal models. This last line of evidence is obviously the most critical. The first studies were done by Carew and colleagues³⁴ and by Kita and coworkers³⁵ using LDL receptor-deficient rabbits. Both groups showed that probucol, previously shown by Parthasarathy and associates³⁶ to be a potent antioxidant, inhibited lesion development by 50–80% in young rabbits

lacking the LDL receptor. Because probucol does have a cholesterol-lowering effect, even in receptor-deficient animals, Carew and coworkers gave a low dose of a 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) reductase inhibitor to their control rabbits to keep the cholesterol levels of the two groups matched. Thus it could be concluded that the protective effect of the probucol was not due to cholesterol lowering but to some other property, presumably its antioxidant property. Since these early studies, many additional intervention trials in experimental animals have been reported. These include additional studies in receptor-deficient rabbits, studies in cholesterol-fed rabbits, and studies in cholesterol-fed nonhuman primates (reviewed in reference 37). Recently, antioxidants have also been shown to be effective in mouse models of atherosclerosis.^{38–42} All in all, 29 studies have been done, of which 21 are strongly positive. Moreover, different antioxidant compounds have been used by different investigators. These included probucol, butylated hydroxytoluene, N,N'-diphenylphenylenediamine, and vitamin E. The fact that antioxidants, some of them differing quite markedly in their chemical structures and properties, all share the ability to inhibit atherosclerosis strongly supports the interpretation that it is their common antioxidant activity that is operative. However, there is always the possibility that they have additional properties that contribute to or may even account for most of their antiatherogenic potential.

Epidemiologic evidence of several kinds is consistent with the antioxidant hypothesis. Population studies have shown that a high dietary intake or a high plasma concentration of antioxidants (vitamin E, vitamin C, β -carotene, or selenium) is associated with a lower risk of CHD.⁴³ Prospective within-population studies have also yielded statistically significant associations^{44,45}; however, the possibility of confounding factors can never be completely dismissed. Moreover, epidemiologic correlations, no matter how strong, cannot establish a causal relationship. Therefore, large, double-blind, randomized clinical intervention trials are needed to settle the question of whether or not antioxidants can provide significant protection against CHD.

Although a number of clinical intervention trials are underway, only a few have been fully reported as of this writing. A Finnish study of α -tocopherol and β -carotene was designed to test the possible effects of these vitamins against cancer.⁴⁶ Administration of 50 mg of vitamin E daily, or 20 mg of β -carotene daily, or both, failed to decrease cancer incidence (and may even have increased it). Cardiovascular endpoints, although not a part of the original hypothesis, were also recorded. There was no decrease in CHD deaths and there was a small but significant increase in hemorrhagic stroke among the men taking vitamin E. The dose of vitamin E used in this study was probably too small. The results of prospective studies show that only individuals taking vitamin E supplements and having a mean vitamin E intake over 100 mg/d were protected significantly against CHD.^{44,45} Moreover, the Finnish study was done in middle-aged men who were heavy smokers and whose lesions must have been far advanced at the time the study was started. Three additional large, double-blind, placebo-controlled vitamin E intervention trials have now been reported. One was strongly positive and two were negative. The Cambridge Heart Antioxidant Study (CHAOS) was a study of 2002 patients with angiographically proved coronary artery disease randomized either to vitamin E (400–800 IU daily) or to placebo.⁴⁷ Median follow-up was 1.4 years. The primary endpoint was the combination of cardiovascular death plus nonfatal myocardial infarction. This was reduced by almost 47% ($p = 0.005$). However, there was no decrease in all-cause mortality.⁴⁷ The

TABLE 11-1. Current Status of the Oxidative Modification Hypothesis

- It rests on a well-defined, mechanistically plausible theoretical footing.
- It is consistent with many phenomena demonstrated in cell culture and in experimental animals.
- It is supported by epidemiologic data, both observational and prospective.
- It is strongly supported by positive intervention studies of atherosclerosis in animal models.
- It is supported by the results of the CHAOS trial⁴⁷ but not by the three clinical intervention trials with vitamin E so far reported.^{46,48,49}
- Only additional appropriately-designed, large double-blind clinical intervention trials will establish the validity of the antioxidant hypothesis in humans. Trials should emphasize stopping the disease in its early stages.

HOPE trial randomized over 9000 patients in a 2×2 factorial design to evaluate the effects of an angiotensin-converting enzyme inhibitor and vitamin E (400 IU/d). In a 5-year follow-up there was no difference in cardiovascular events between the controls and those on vitamin E.⁴⁸ The GISSI trial randomized almost 3000 patients to placebo or vitamin E (300 mg/d). Over a 3.5-year follow-up there was no difference in major cardiovascular endpoints due to vitamin E.⁴⁹

The effectiveness of β -carotene has been tested in three large-scale studies and none has shown any effect on cardiovascular events.^{46,50,51} However, whereas the doses of vitamin E used in the intervention trials discussed above are adequate to protect circulating LDL against *ex vivo* oxidation, β -carotene does not do that even at the large doses used in these studies.^{52,53} β -carotene does not seem to function as an antioxidant in this context. Consequently, these trials do not constitute tests of the oxidative modification hypothesis.

It should be emphasized that the experimental animal data relate almost exclusively to fatty streaks. In these animal models, lesions seldom go on to more advanced stages during the relatively short course of the study. Thus the experimental evidence is only that antioxidants may inhibit *fatty streak formation*. There is no experimental evidence that antioxidants will have an effect on fibrous plaques or complicated lesions. Eventually, of course, inhibition of fatty streak formation should be reflected by a reduction in the number of fibrous plaques and complicated lesions. However, to see effects on these later lesions may require a longer period of study than the generally accepted 5 years.

It is too early to draw conclusions regarding the effectiveness of antioxidants against human atherosclerosis. However, the strength of the experimental basis for the antioxidant hypothesis justifies continued exploration of its relevance to human disease, and a number of studies are currently in progress.

ATHEROSCLEROSIS IN DIABETIC SUBJECTS

Many studies have been carried out to determine whether the atherosclerosis in diabetic subjects might be qualitatively distinct, which could shed some light on the reason for the excess morbidity from atherosclerosis in persons with diabetes mellitus. None of these studies demonstrates qualitative differences—just more lesions that occur earlier.⁵⁴ The histologic appearance of the lesions, their gross appearance, their chemical composition, their sites of predilection, and the clinical expression of the disease are almost exactly the same in diabetic patients and in nondiabetics. One possible exception that calls for special comment is the apparently greater frequency of peripheral vascular disease in diabetic subjects; however, this may be more apparent than real. It is possible that the combination of macrovascular and microvascular disease (or the combination of macrovascular disease and peripheral neuropathy) accounts for the more serious clinical presentation of impaired peripheral circulation in the diabetic. It is of interest that peripheral vascular disease in the diabetic is more closely correlated with the duration of the disease, degree of hyperglycemia, and presence of microvascular disease than is atherosclerosis affecting the coronary or cerebral vessels.^{55–57} Janka and associates⁵⁷ found that disease below the knee was related to these factors, but that disease above the knee correlated better with hypercholesterolemia, hypertension, and cigarette smoking, the classical risk factors for large-vessel disease. These findings tend to support the conclusion that peripheral vascular disease is more of a clinical

problem in diabetics because of interactions between microvascular disease (or neuropathy) and macrovascular disease.

In diabetic subjects, just as in nondiabetic subjects, the risk of clinically evident atherosclerosis increases among cigarette smokers, the obese, hypertensives, those with low HDL values, and those with high LDL values. This concordance with regard to risk factors does not rule out the presence of differences of some kind but is compatible with the premise that the disease is qualitatively no different in diabetic patients.

This conclusion is consonant with the fact that in populations where the general incidence of CHD is low, the incidence in the diabetic population there is also low. For example, in Japan, where the prevalence of CHD in the general population is low, it is also low in the diabetic population and one-sixth the prevalence among Americans with diabetes.⁵⁸ Whatever environmental or genetic factors account for the overall lower prevalence of CHD appear to affect its prevalence within the diabetic population in like fashion. A key corollary to this is that interventions that decrease CHD morbidity and mortality in the general population will probably do so also, and to a comparable degree, within the diabetic population. Unfortunately, some physicians tend to regard the development of macrovascular complications as an inevitable accompaniment to diabetes mellitus, not amenable to prevention by intervention. This is not the case. Because the disease process is not qualitatively different, it can be anticipated that the beneficial results already demonstrated in the general population as a result of cholesterol lowering, cessation of smoking, and treatment of hypertension can be expected to be equally impressive within the diabetic population. Once we can identify the reasons the disease progresses more rapidly in diabetic patients, we can hope to intervene more specifically and get even better results.

Some CHD risk factors are found clustered with a high frequency in type 2 diabetes. The constellation of glucose intolerance associated with insulin resistance, hypertension, hypertriglyceridemia with low HDL, and central obesity is variously designated as Syndrome X,⁵⁹ the deadly quartet,⁶⁰ the insulin resistance syndrome,⁶¹ or the plurimetabolic syndrome. How these elements are related in pathogenetic terms is not clear. Most of these features are associated with obesity,^{62,63} even in the absence of frank diabetes. However, some type 2 diabetes patients have most of the elements of the syndrome without obesity.⁶⁴ Until the causal relationships are sorted out, one can only treat these abnormalities individually as in nondiabetic patients with these risk factors.

In summary, if there are any differences in the basic nature of the atherosclerotic process in diabetes, they must be subtle. The bulk of the evidence available suggests that the basic nature of the atherosclerotic process in diabetes is the same except that everything moves at a faster rate. If that premise is valid, our goal is to find out what gets speeded up and how and when it happens. The risk factors are the same ones identified in nondiabetic persons. All of them should be treated intensively, even more intensively than in nondiabetic patients. However, the known risk factors simply cannot account for all of the increased risk in diabetic patients.

INTERSECTIONS BETWEEN DIABETES AND ATHEROSCLEROSIS

We should start this section by stating that no one knows with any certainty why diabetic patients suffer premature macrovascular disease. The reader who is interested in knowing what the possibilities are, and which are favored, is invited to read on.

Dyslipidemia

The disturbances in lipoprotein patterns found in diabetes are discussed in Chap. 47, so the discussion here will be brief. Diabetic patients in good control do not have hypercholesterolemia any more frequently than the general population.⁶⁵ However, they do have some degree of hypertriglyceridemia as well as low HDL levels (still lower when poorly controlled).⁶⁵ Exactly how atherogenic the triglyceride-rich lipoproteins are remains a matter of controversy. They certainly have not been exonerated and the hypertriglyceridemia in diabetes may be highly relevant. A low HDL level is the most powerful predictor of coronary artery disease and could play a significant role in the premature atherosclerosis of diabetes mellitus. Because hypertriglyceridemia and low HDL are closely linked, it has been difficult to assign primacy to one or the other until quite recently. The demonstration that transgenic mice with overexpression of apoA-1 are resistant to atherosclerosis strongly supports a direct effect of low HDL on susceptibility to atherosclerosis.⁶⁶ Whether it is the whole story or not is not known. Triglyceride-rich lipoproteins may be directly atherogenic as well. Thus, dyslipidemia may be a contributing factor to the premature atherosclerosis in some diabetic persons. On the other hand, there are many diabetic patients who do not have dyslipidemia but in whom premature atherosclerotic disease is present. Possible contributing factors in these cases are discussed in the following sections.

Lipoprotein Oxidation

Pioneering studies by Sato and associates⁶⁷ and by Nishigaki and coworkers⁶⁸ showed some years ago that the plasma lipoproteins of patients with diabetes showed higher concentrations of oxidation products. Studies in diabetic animal models, mostly streptozotocin-treated animals, show that there is an increase in oxidized lipids in the plasma lipoproteins and red cell membranes, and that this increase can be prevented by treating the animal with an appropriate antioxidant (see review by Chisolm and coworkers⁶⁹). Thus, to the extent that oxidative modification plays a role in atherogenesis, diabetic subjects might be at a higher risk.

There is a very direct connection between diabetes and oxidative damage: oxidation of LDL proceeds more rapidly in the presence of high levels of glucose, and the rate of generation of glycated proteins is accelerated under pro-oxidant conditions.⁶⁹⁻⁷³ There appears to be a basis for a logarithmic progression: hyperglycemia favoring oxidation of lipids on the one hand, and pro-oxidant conditions and oxidized lipids favoring the formation of advanced glycation end-products on the other. It is of interest that in atherosclerotic lesions one finds both oxidized LDL and advanced glycation end-products,⁷⁴⁻⁷⁶ compatible with an interaction of the kind just discussed.

Nonenzymatic Glycation

Glucose and other aldoses react nonenzymatically with amino groups to form glucose-protein linkages. The rate of nonenzymatic glycation is proportional to the glucose concentration and it proceeds more rapidly in diabetic patients, especially when their control is poor. All of the plasma proteins, and probably all of the cell surface membrane proteins, are also candidates for glycation. Witztum and coworkers⁷⁷ demonstrated that LDL underwent glycation and that this decreased its affinity for the native LDL receptor, consequently prolonging its lifetime in the plasma compartment. Simply prolonging the lifetime of the LDL would increase the proba-

bility of its undergoing oxidative modification with the adverse consequences already discussed. Glycation of connective tissue matrix proteins, particularly when extensive, could increase the probability that LDL will be trapped in the vessel wall and there undergo more extensive oxidative modification and further glycation.⁷⁸ The early steps in glycation are reversible, but if it continues, it gives rise to advanced glycation end-products (AGEs). These compounds, heterogeneous in structure and not completely defined chemically, form cross-linkages among macromolecules, are fluorescent, and importantly, are recognized by receptors on the cell surface. A strong case has been made for the possibility that the microvascular complications of diabetes mellitus may be due to the accumulation of AGEs. More recently, evidence has accumulated that the macrovascular complications also may be in part attributable to AGEs. These lines of evidence and the chemistry and pathophysiology of AGEs are explored in detail in Chap. 13. Here we only point to the intersections between AGEs and our current schema for atherogenesis.

Trapping of LDL in the subendothelial space is a critical step in the early stages of atherosclerosis. LDL binds readily to proteoglycans, collagen, elastin, and other matrix proteins, but it binds even more strongly when these matrix proteins carry AGEs.⁷⁸ Oxidative modification of such trapped LDL would make it a ligand for uptake by macrophages in the subendothelial space. Also, the additional trapping may encourage the formation of LDL aggregates, also excellent ligands for macrophage phagocytosis.⁷⁹

Another category of interaction, as reviewed by Vlassara,⁸⁰ may result from the effects of AGEs on vascular wall cells via specific receptors that recognize them. For example, AGE receptors on the endothelial cell can activate NF- κ B, a transcription factor that is also stimulated by oxidized LDL. AGEs in soluble form are chemotactic for monocytes and activate them. They increase the production of PDGF, IGF-1, IL-1, and TNF, all of which have been implicated as contributing to the chronic inflammatory process in an atherosclerotic lesion. As discussed, glycation and lipid oxidation may be reciprocally interactive and synergistic. There is evidence that glycated proteins are more susceptible to oxidative modification and, vice versa, that lipoproteins that have been oxidized are more susceptible to glycation. It is interesting that the complex cross-linking that characterizes AGEs is in a rough way analogous to the cross-linking that characterizes oxidatively modified lipoproteins or oxidatively damaged membranes.

If the mechanisms discussed above were important in the accelerated atherosclerosis of diabetes, it could be anticipated that there would be a good correlation between the level of glycemia and the CHD risk (or other measures of greater progression of atherosclerosis). Some epidemiologic studies show that hyperglycemia is a risk factor for CHD, but the link is not certain. Studies in which glycemia has been carefully controlled, as in the UGDP study, with administration of variable doses of oral agents and insulin in type 2 diabetes,⁸¹ or the Diabetes Control and Complications Trial (DCCT) in type 1 diabetes,⁸² have not shown a decrease in CHD mortality, but neither study was designed to test the hypothesis. Both were focused on other complications. There is a need for a large, double-blind test of whether or not close glycemia control reduces the CHD risk in diabetes.

Monocyte/Macrophage Function

Monocytes play a key role in the early stages of fatty streak formation and are the major source of foam cells. It is recognized that di-

abetic patients have difficulty fighting infections, suggesting the possibility of defects in leukocyte function. Abnormalities in neutrophil function have been described, but the situation with respect to monocyte function is less clear. Recently it has been shown that exposure of cultured endothelial cells to high levels of glucose increases monocyte binding⁸³ and that endothelial cells in diabetic rabbits overexpress VCAM-1 *in vivo*.⁸⁴ Also, monocytes from patients with diabetes show an increased adhesion to normal endothelial cells in culture, and this is attributed to overexpression of β_2 integrins.⁸⁵ Monocytes prepared from patients with recent onset of type 1 diabetes showed *less* expression of certain adhesion molecules (LFA-1 α , ICAM-1, and HLA-DR). Stewart and coworkers⁸⁶ observed a small but statistically significant *decrease* in expression of surface receptors on monocytes from type 1 diabetics with ketoacidosis.

Another mechanism that could link diabetes to atherosclerosis is the chemotactic activity of AGEs.⁸⁷ These products of protein glycation exert a chemotactic effect for human blood monocytes and selectively induce monocyte migration across an intact endothelial cell monolayer. When these transmigrating monocytes interact with the AGEs in the matrix, they increase their production of PDGF. Thus the progressive accumulation of glycation products in the subendothelial space could contribute to the progression of the lesion.

Hiramatsu and Aramori⁸⁸ reported that monocytes from diabetic patients, especially hypertriglyceridemic diabetic patients, show an increase in the rate of superoxide production. It would be of great interest to extend studies of this kind to determine the enzyme systems responsible for the observed increase in rate of LDL oxidation. The combination of an increase in the ability of cells to oxidize LDL and the greater ease with which LDL is oxidized in the presence of high glucose concentrations could represent a significant driving force for LDL modification in diabetic persons, contributing to their advanced atherosclerosis.

Diabetes may have implications for the later stages of atherogenesis, including the terminal fatal thrombosis. A number of platelet abnormalities have been described, but whether they are causative or reflect underlying vascular disease remains uncertain.⁸⁹ The fatal thrombosis is often triggered by erosion of the fibrous cap, exposing blood to tissue factor and other thrombogenic factors in the lipid core of the lesion. This rupture generally occurs at the shoulder of the lesion where there are higher densities of macrophages. On a purely speculative level, if the monocyte/macrophages in diabetic patients were less robust and more inclined to lyse and spill their contents or to release lytic enzymes at a higher rate than macrophages in normal patients, this could explain the higher frequency of clinical events in diabetics. Because there is evidence to suggest that the conversion from a fatty streak to a fibrous plaque is linked to loss of endothelial cells, here might be another way in which the lesions in diabetics advance more rapidly than those in nondiabetic subjects.

Immune Mechanisms

There is mounting evidence that the immune system influences the rate of progression of atherosclerosis. First, autoantibodies against glycated LDL⁹⁰ have been demonstrated in both normal subjects and, at higher titers, in diabetic subjects. Autoantibodies against oxidized LDL are also present in the plasma of both diabetic and nondiabetic patients.⁷⁵ Immune complexes of oxidized LDL have been demonstrated in atherosclerotic lesions in receptor-deficient

rabbits.⁹¹ Such immune complexes can be recognized by the Fc receptor and provide an additional pathway for rapid uptake and foam cell formation.⁹² Immune complexes are potentially cytotoxic and could in this way favor the progression of lesions. Salonen and coworkers⁹³ reported that in a small series of cases the rate of progression of carotid artery intima/media thickness was closely correlated with the titer of autoantibody against oxidized LDL. Associations of this kind, however, do not necessarily establish a causal relationship and further studies are needed. Palinski and coworkers⁹⁴ recently found that deliberately increasing the titer of antibody against oxidized LDL in receptor-deficient rabbits by immunizing them with exogenously oxidized LDL *slowed* rather than *speeded* the progression of early lesions. They suggest that the very high titers reached may have been beneficial by "scavenging" oxidized LDL from the system at early stages and preventing some of the deleterious effects that might otherwise occur. Jonasson and coworkers⁹⁵ have shown that T lymphocytes are almost universally present in atherosclerotic lesions. Further studies showed that these include a small percentage of clones that are activated specifically by oxidized LDL.⁹⁶ The precise role of T cells in atherogenesis remains uncertain. Hansson and coworkers⁹⁷ have shown that a sharp drop in circulating T cells, induced by the injection of a monoclonal antibody against them, actually results in larger proliferative lesions in balloon-catheterized rat aortas. Clearly, additional research needs to be done to resolve this complex problem. Nevertheless, the evidence provided thus far suggests that diabetic patients, because they do have higher titers of antibodies against glycated LDL and other glycated proteins, may be more susceptible.

Abnormalities in Connective Tissue Matrix

We have discussed the possibility that AGEs may contribute. El Khoury and coworkers⁹⁸ showed that macrophages do not show calcium-independent binding to native collagen IV but do bind to glycated collagen IV. Interestingly, this binding occurred via the acetyl LDL receptor. Previous studies by Fraser and coworkers⁹⁹ showed that this receptor is also the means that macrophages use to attach to plastic dishes in a calcium-independent fashion.

It is possible that the biosynthesis and secretion of proteoglycans, collagen, elastin, or other connective tissue matrix elements may be abnormal in diabetes independently of the nonenzymatic glycation that leads to AGEs. Because trapping of LDL in the artery wall is believed to play an important role in atherogenesis, abnormalities in connective tissue matrix biosynthesis and deposition that enhance such trapping could be proatherogenic.

Relationship between Microvascular and Macrovascular Disease

There has been a tendency to regard microvascular and macrovascular disease as independent and unrelated. However, this is by no means established. We have discussed some of the metabolic links that are emerging as more is learned about the pathogenesis of atherosclerosis. For example, there is now evidence that AGEs may be involved in both the microvascular and macrovascular complications. There is evidence that hyperglycemia may favor the oxidation of LDL and thus could play a role in both macrovascular and microvascular disease. However, intervention trials have yielded negative, or at best borderline, evidence for a decrease in CHD risk with tight control of hyperglycemia.^{100,101} A definitive answer must await further large-scale studies to determine whether control of

hyperglycemia can decrease the progression of atherosclerosis in diabetic subjects (independent of control of hyperlipidemia or other risk factors).

A unifying hypothesis is always preferable when possible. A possibility that has received little attention is that the vasa vasorum are also subject to microvascular disease, and that this is what enhances the rate of progression of macrovascular disease in the diabetic patient. The oxygen supply and nutrition of the arterial wall in large vessels arise in part from the vasa vasorum. It is well established that even the most mild noxious stimulus on the adventitial side of the artery produces cellular changes in the intima. Certainly the possibility that disease of the vasa vasorum plays a role in atherosclerosis has not been ruled out. However, there are no definitive experiments that assess the relative importance of the vasa vasorum in atherosclerosis either in nondiabetic or diabetic persons. Further research in this area would certainly be warranted.

SUMMARY

Myocardial infarction and other macrovascular diseases are responsible for more deaths in diabetic patients than all of the other causes of death combined. The lesions in diabetic subjects are qualitatively indistinguishable from those in nondiabetic patients, but the rate of progression of the disease is greater and the incidence of fatal outcome higher. The new guidelines on management of hyperlipidemia issued by the National Cholesterol Education Program recommend that diabetic patients should be treated just as aggressively as patients with established coronary heart disease (LDL goal <100 mg/dL).¹⁰² The past decade has seen some remarkable progress in our understanding of vascular pathobiology, such that we can now delineate in some detail the critically important events in atherogenesis. As a result, we can now postulate explicit ways in which diabetes may lead to an acceleration of the atherogenic process. Among the more attractive of these is the interrelationship between glycation and oxidation. Hyperglycemia can promote both the oxidative modification of LDL and the rate of formation of glycated proteins. We still are not in a position to say whether precise control of blood glucose levels will reduce the risk of atherosclerosis and its complications in the diabetic. However, the circumstantial evidence supporting this possibility strengthens the case for rigorous control of hyperglycemia. Most important, management of *all* of the conventional risk factors for atherosclerosis in diabetic patients should rank as high as control of hyperglycemia.

Endothelial Dysfunction and Vascular Thrombosis in Diabetes

Douglas E. Vaughan

Patients with diabetes mellitus are at increased risk for a variety of cardiovascular disorders, including myocardial infarction and stroke.¹ The risk for cardiovascular disease is increased up to four-fold among diabetic patients compared with nondiabetic persons. Diabetes is a particularly strong determinant of cardiovascular risk in women. The impact of vascular disease on patients with diabetes mellitus is staggering and accounts for nearly 80 percent of deaths and greater than 70 percent of hospitalizations for patients with this common metabolic disorder. The reasons for this increased risk of atherothrombotic events are widely discussed but only incompletely understood. There is a strong association between the metabolic abnormalities seen in diabetes mellitus and the development of premature atherosclerosis that is reviewed elsewhere in this text. Certainly many of the macrovascular complications of diabetes appear in conjunction with and may reflect the presence of advanced atherosclerosis. In parallel with the development of atherosclerosis, other independent factors coconspire to increase the risk of ischemic cardiovascular events in patients with diabetes. This chapter focuses on the role of endothelial dysfunction and the increased thrombotic tendency found in diabetes.

ENDOTHELIAL DYSFUNCTION IN DIABETES

The vascular endothelium participates in a number of physiologic processes that contribute to vascular health.² One of the most important functions involves the production of short-lived vasodilators in response to physiologic stimuli. These vasodilators include nitric oxide, prostacyclin, and endothelial-dependent hyperpolarizing factor (EDHF). The production of nitric oxide (NO) by the vascular endothelium has been the subject of intense investigation for the last two decades. In addition to the important role NO plays in the regulation of vascular tone, NO helps maintain the integrity of the blood vessel wall and blood fluidity by preventing monocyte adhesion and platelet aggregation. NO also retards the growth of vascular lesions by inhibiting cellular proliferation.³ Taken together, these pleiotropic effects of NO suggest that endothelial NO production may play a pivotal role in the prevention of vascular disease. Although endothelial dysfunction is widely discussed in the context of impaired endothelium-dependent relaxation, impairment of endothelial function also likely impacts on other important physiologic endothelial functions that protect the vasculature from inflammatory processes and thrombosis. Endothelium-dependent

vasodilation and, specifically, the production of NO, is impaired in diabetes. This has been shown in experimental models of chemically induced diabetes⁴⁻⁷ as well as in genetic models of type 1 diabetes.^{8,9} In experimental models, the totality of evidence indicates that the normal vascular relaxation response to nitrates is preserved while agonist-stimulated endothelium-dependent vasodilator function is impaired. The impairment in the endothelial vasodilation can be seen in both conduit and resistance arteries and cannot be explained by physiologic changes in smooth muscle cell responsiveness to NO or by changes in guanylate cyclase reactivity.¹⁰

There is also substantial clinical evidence that NO-mediated vasodilation is impaired in patients with type 1 diabetes^{11,12} and type 2 diabetes mellitus.¹³ Abnormalities in vascular reactivity and biochemical markers of endothelial cell activation are present early in individuals at risk of developing type 2 diabetes, even at a stage when normal glucose tolerance exists.¹⁴ Endothelium-dependent vasodilation has also been reported to be impaired in first-degree relatives of patients with type 2 diabetes.¹⁵ The question arises as to the mechanisms through which diabetes impairs endothelial vasodilator function and specifically alters NO production or bioavailability. It has been shown that hyperglycemia *per se* acutely attenuates endothelium-dependent vasodilation in healthy subjects.¹⁶ There are several factors that probably contribute to impaired vasodilation in diabetes over the long term. Diabetes and the metabolic abnormalities that accompany this disorder may reduce endothelial NO production in response to physiologic stimuli. This may be explained by direct effects of advanced glycosylation end products on endothelial NO production¹⁷ or by a relative deficiency of the NO synthase cofactor tetrahydrobiopterin in diabetes.¹⁸ Oxidative degradation of endothelium-derived NO contributes to abnormal endothelium-dependent vasodilation in animal models of diabetes mellitus.¹⁹

The vascular impairment in NO production seen in diabetes also likely has other important ramifications that impact upon the development of cardiovascular disease. Impairment of NO production enhances the progression in atherosclerosis in animal models.^{20,21} Indeed, NO plays an important role in preventing monocyte adhesion to the blood vessel wall, which is one of the initial steps in the development of atherosclerotic lesions. NO possesses other important vasculoprotective properties, and serves as an endogenous inhibitor of smooth cell proliferation and platelet activation.²² Recently it has been shown that NO also plays a role in enhancing the anticoagulant properties of the vascular endothelium

by suppressing the production of plasminogen activator inhibitor type-1 (PAI-1).²³

Clinical Ramifications

Although this issue has not been selectively examined in diabetes, coronary endothelial vasodilator dysfunction predicts long-term atherosclerotic disease progression and cardiovascular events.^{24,25} At present, there is a paucity of data regarding the reversal of endothelial dysfunction in diabetes. Endothelial dysfunction in forearm resistance vessels of patients with type 2 diabetes mellitus can be improved by administration of the antioxidant vitamin C.^{19,26} These findings support the hypothesis that NO inactivation by oxygen-derived free radicals contributes to abnormal vascular reactivity in diabetes. In the future, the assessment of forearm and/or coronary endothelial vasoreactivity may gain wider acceptance as both a diagnostic and prognostic tool in patients at risk for coronary heart disease.²⁷ At present, these measurements remain experimental tools.

DIABETES AND THROMBOSIS

Patients are defined as having a hypercoagulable state if they have laboratory abnormalities or a clinical condition that is associated with increased risk of thrombosis.²⁸ Certainly patients with diabetes mellitus meet this definition. As noted previously, the vascular endothelium, which is a primary component of the defense against intravascular thrombosis, is dysfunctional in patients with diabetes. The impaired production of NO and prostacyclin seen in diabetes is very likely an important factor in the increased activation of platelets and clotting factors also seen in diabetes. Specifically, with regard to coagulation, there are number of pieces of evidence to indicate that coagulation is enhanced in patients with diabetes mellitus. Several small studies indicate that subclinical evidence of thrombosis can be identified in plasma from diabetic patients by measuring coagulation activation markers such as prothrombin activation fragment 1 + 2 and thrombin/antithrombin complexes.^{29–33} With regard to specific coagulation factors, perhaps the strongest epidemiologic evidence indicates that elevated fibrinogen levels are a risk factor for ischemic cardiovascular events.³⁴ Patients with diabetes generally have elevated plasma fibrinogen levels compared to healthy control subjects, and this may explain some of the increased risk for cardiovascular disease in diabetes.³⁵ The mechanism for this increase has not been well studied. Fibrinogen is an acute phase reactant, and the increase seen in diabetes may reflect low-level inflammation.³⁶ Intravascular volume depletion in uncontrolled diabetes may also account for some of the observed increase in plasma fibrinogen. No direct effects of insulin or glucose on fibrinogen production have been described. In addition to fibrinogen, plasma levels of many coagulation factors are modestly increased in diabetes, including factors VII, VIII, XI, and XII and von Willebrand's factor.³² The significance of these increases is debatable, although in epidemiologic studies, increased levels of factor VII do appear to increase the risk of coronary events.³⁷ The increased tendency to thrombosis in diabetes may also reflect a failure in circulating anticoagulant mechanisms. Although there is no evidence of important reductions in plasma levels of antithrombin III or heparin cofactor II, it has been reported that the plasma level of activated protein C is reduced in diabetes.³⁸ However, results from other studies reported increased or

unchanged protein C levels in patients with diabetes compared with healthy control subjects.^{39–42}

Another system that more likely contributes to the increased thrombotic risk in diabetes is the impairment in endogenous fibrinolytic function seen in patients with type 2 diabetes. The mammalian fibrinolytic system serves as one of the endogenous defense mechanisms against intravascular thrombosis. It functionally complements the effects of endogenous anticoagulants, such as protein C and protein S, and the short-lived endothelium-derived platelet inhibitors NO and prostacyclin. The activity of the fibrinolytic system is ultimately dependent on the generation of the protease plasmin, which is produced from the inactive precursor plasminogen by the action of plasminogen activators. Humans possess two distinct plasminogen activators, tissue-type plasminogen activator (t-PA) and the urokinase-type plasminogen activator (u-PA). Although both of these activators are synthesized in endothelium, t-PA appears to be primary plasminogen activator in the vasculature. It has been proposed that the plasminogen activator system is a critical defender against intravascular thrombosis in the coronary circulation,⁴³ and the balance between t-PA and its endogenous inhibitor, plasminogen activator inhibitor 1 (PAI-1) is a major determinant of net fibrinolytic activity.

Physiology of PAI-1

PAI-1 is a globular protein comprised of 379 amino acids in a single chain.⁴⁴ PAI-1 belongs to the superfamily of serine protease inhibitors (serpins),⁴⁵ and as such, it is structurally similar to other serpins including ovalbumin, angiotensinogen, antithrombin III, and α_2 -antiplasmin.

Active PAI-1 is readily cleaved by, and forms complexes with, t-PA. The reaction is quite rapid and proceeds with a second-order rate constant of $10^7 \text{ M}^{-1} \text{ s}^{-1}$.⁴⁶ A series of studies involving site-specific mutagenesis have revealed that PAI-1 interacts with t-PA via a two-step mechanism. Replacement of three positively charged amino acids (Lys₂₉₆, Arg₂₉₈, and Arg₂₉₉) in t-PA with negatively charged glutamic residues generates a t-PA mutant that retains its ability to activate plasminogen and is highly resistant to inhibition by PAI-1.⁴⁷ The first step in the interaction between t-PA and PAI-1 is reversible and appears to involve an electrostatic interaction between positively charged amino acids in t-PA and negatively charged residues in PAI-1 that are located on a surface loop (residues 350–355). The second step of the interaction of PAI-1 with t-PA is irreversible and involves the cleavage of the PAI-1 reactive site by the active site of t-PA. In addition to its role as the primary inhibitor of t-PA in plasma, PAI-1 also promotes thrombosis by inhibiting activated protein C.

PAI-1 circulates in low but measurable concentrations in plasma, at less than 4:1 molar excess to that of t-PA.⁴⁸ The source of plasma PAI-1 is debatable, as it is synthesized in the vascular endothelium and smooth muscle cells, in the liver, and in adipose tissue.^{49,50} Platelets also store large quantities of PAI-1 that are secreted following platelet aggregation.⁵¹ Several different fates are possible for PAI-1 after it is secreted. The circulating half-life of PAI-1 is approximately 5 minutes,⁵² and the majority of PAI-1 likely circulates briefly in plasma and is removed via a hepatic clearance mechanism. A fraction of secreted, active PAI-1 reacts with plasma t-PA and forms inert, insoluble complexes. There appears to be no endogenous mechanism for recycling t-PA–PAI-1 complexes, which are cleared via receptor-dependent mech-

anisms.⁵³ Active PAI-1 can also bind to vitronectin, which actually stabilizes PAI-1 in the active conformation.⁵⁴ Binding to vitronectin has also been found to broaden the reactive specificity of PAI-1. Specifically, vitronectin endows PAI-1 with thrombin inhibitory properties.⁵⁵

Endothelial cells also have the capacity to secrete PAI-1 abnormally.⁵⁶ In the extracellular matrix of blood vessels, PAI-1 likely plays a role in vascular remodeling. The relative abundance of vitronectin in the subendothelial matrix provides a mechanism for preserving PAI-1 activity, and, in fact, the PAI-1–vitronectin complex may represent the physiologically relevant form of the inhibitor in the extracellular matrix.

A wide array of cytokines, growth factors, and hormones have been found to stimulate endothelial PAI-1 production. Inflammatory cytokines such as interleukin-1 (IL-1) and tumor necrosis factor α (TNF- α)⁵⁷ are potent regulators of PAI-1 production. With acceptance of the concept that atherosclerosis is predominantly an inflammatory process,⁵⁸ this functional linkage between PAI-1 and inflammatory cytokines may help explain the increase in PAI-1 reported in atherosclerosis. Transforming growth factor β (TGF- β) is recognized as an important stimulus for the production of PAI-1 in tissues,⁵⁷ and this interaction has important ramifications for the understanding of the pathogenesis of vascular fibrosis and nephrosclerosis in diabetes.⁵⁹ Thrombin is also a potent stimulus for PAI-1 production in cultured endothelial cells.⁶⁰ Angiotensin II⁶¹ and its hexapeptide metabolite angiotensin IV induce dose- and time-dependent increases in endothelial PAI-1 mRNA expression *in vitro*.⁶² Angiotensin II is also a potent stimulus of vascular PAI-1 production *in vivo*.^{63,64}

The increased production of PAI-1 seen in patients with diabetes has been attributed directly to glucose,^{65,66} insulin,⁶⁷ and triglycerides. In the upstream regulatory region of the PAI-1 gene, specific sequences have been localized that respond to VLDL⁶⁸ and to glucose.⁶⁹ Indeed, PAI-1 is one of several genes with transcription that is induced by high glucose concentrations. The glucose-responsive region of the PAI-1 promoter resides in two Sp1 sites located within 90 bases of the transcription start site. Recent studies indicate that hyperglycemia induces mitochondrial superoxide production, which in turn increases hexosamine synthesis and O-glycosylation of Sp1.⁷⁰ This modification induces a dephosphorylation in Sp1, which has been hypothesized to reduce interactions with transcriptional repressor proteins, thus yielding increased Sp1-dependent gene transcription. Insulin and proinsulin peptides also induce PAI-1 production, which may contribute to increased PAI-1 production in the setting of insulin resistance.

Clinical Consequences of Increased PAI-1

Theoretically, an excess of PAI-1 will reduce the efficiency of the fibrinolytic system, which may create a permissive environment for vascular thrombosis. There is a growing body of evidence that PAI-1 excess (usually measured as PAI-1 activity) may in fact be a risk factor for venous thromboembolic disorders and for ischemic cardiovascular disease.⁷¹ Elevated levels of PAI-1 appear to be a risk factor for recurrent deep vein thrombosis.⁷² PAI-1 excess has been identified in youthful survivors of acute myocardial infarction⁷³ and levels are higher in MI survivors that go on to develop recurrent MI.⁷⁴ Low plasma fibrinolytic activity, which may be a reflection of increased PAI-1 activity, appears to be a leading determinant of risk for ischemic heart disease in younger men.⁷⁵ There is

compelling evidence that excess PAI-1 is present in atherosclerotic human blood vessels.⁷⁶ Vascular PAI-1 content is increased in diabetes and in atherectomy specimens from patients with diabetes compared to healthy control subjects.⁷⁷ This finding is relevant to the present discussion in view of the role plasmin plays in “vascular housekeeping.” Plasmin activates several different matrix metalloproteinases that are needed to degrade extracellular matrix proteins, including collagen and other glycoproteins.⁷⁸ Plasmin itself plays a role in vascular housekeeping by degrading local fibrin deposits, collagen, and fibronectin. Plasmin also plays a role in the activation of the multifaceted cytokine TGF- β , which is felt to have antiatherosclerotic effects related to its antimitogenic properties.⁷ Thus, by virtue of these mechanisms and potentially others, an excess of PAI-1 in vascular tissue reduces local plasmin production and diminishes vascular housekeeping capacity. Recent work indicates that PAI-1 deficiency protects against the development of hypertension and perivascular fibrosis in the setting of long-term NC synthase inhibition.⁸⁰ Thus, the enhanced production of vascular PAI-1 in clinical conditions associated with a relative NO deficiency may accelerate the development of arteriosclerosis and hypertension.

These local vascular and tissue effects of PAI-1 in retarding vascular defense mechanisms against intravascular clotting and atherosclerotic plaque growth deserve additional emphasis with regard to the understanding of the development of atherothrombotic disease in type 2 diabetes. Plasma levels of PAI-1 are elevated in patients with type 2 diabetes, although the cause of this elevation is likely multifactorial in origin. Patients with type 2 diabetes uniformly exhibit insulin resistance that is associated with several cardiovascular risk factors, including systolic hypertension, hypertriglyceridemia, increased hip–girth ratio, glucose intolerance, hyperinsulinemia, and low HDL levels. Plasma levels of PAI-1 have been found to correlate strongly with insulin resistance.⁸¹ As reviewed previously, insulin, proinsulin-like molecules, glucose, and VLDL have been shown to stimulate PAI-1 production *in vitro*. Similar associations have been reported between plasma PAI-1 activity and plasma insulin and triglyceride levels in obese patients,^{82,83} in patients with coronary artery disease,⁸⁴ and in patients with type 2 diabetes.⁸⁵

Genetic factors may also impact on the development of thrombosis in diabetes. For example, a common 4G/5G polymorphism in the PAI-1 promoter has been described.⁸⁶ The 4G allele has been reported to be associated with high plasma PAI-1 activity. Furthermore, the prevalence of the 4G allele is significantly higher in patients with myocardial infarction before the age of 45 years than in population-based control subjects (allele frequencies of 0.63 versus 0.53).⁸⁷ It appears that both alleles are capable of binding a transcriptional activating protein, whereas the normal 5G allele also binds a repressor molecule. Thus, individuals with the 4G polymorphism lose the ability to bind the repressor and exhibit increased plasma levels of PAI-1. Plasma glucose and triglyceride levels also appear to correlate strongly with plasma PAI-1 levels in 4G/4G homozygotes.⁸⁸

Therapeutic Implications

At the present time, thrombolytic agents are the single class of drugs available that are designed to alter fibrinolytic activity directly and acutely. It may be desirable, however, to enhance endogenous fibrinolytic activity for the prevention and treatment of a

variety of thrombotic vascular disorders. This is particularly true when considering ways to prevent the development of vascular disease in patients with diabetes mellitus.

Because PAI-1 plays such a major role in regulating fibrinolytic activity, it is a very attractive therapeutic target. Drugs that reduce plasma insulin levels or that attenuate insulin resistance may have secondary benefits in reducing PAI-1 levels. Metformin has been reported to reduce plasma PAI-1 activity in normal subjects and in patients with type 2 diabetes.^{89,90} Insulin-sensitizing agents, such as thiazolidinediones, reduced plasma PAI-1 levels by nearly 30% in women with impaired glucose tolerance and polycystic ovary syndrome⁹¹ and in subjects with type 2 diabetes.⁹² Because glucose may directly regulate PAI-1 production, especially in individuals with the 4G/4G genotype, improved glycemic control is likely to reduce PAI-1 production over the long term. Other agents may also reduce tissue expression of PAI-1 and may be of benefit in protecting against diabetic complications. ACE inhibitor therapy can significantly reduce plasma PAI-1 levels after MI,^{48,93} and in healthy subjects on a low-salt diet.⁹⁴ We speculate that this effect may contribute to the beneficial effect of ACE inhibitor therapy in reducing the risk of MI, stroke, and cardiovascular mortality in patients with diabetes.⁹⁵ Finally, because NO plays an important role in suppressing vascular PAI-1 production, a unified therapeutic approach to improving vascular health through the restoration and maintenance of endothelial NO production is likely to have compound benefits in the population afflicted with diabetes.

Biochemical Mechanisms of Microvascular Disease

Michael Brownlee

James N. Livingston

INTRODUCTION

Diabetes mellitus is by far the most common serious metabolic disorder, with a worldwide prevalence estimated to be between 1% and 5%. All forms of diabetes, both inherited and acquired, are characterized by hyperglycemia, a relative or absolute lack of insulin, and the development of diabetes-specific microvascular pathology in the retina, renal glomerulus, and peripheral nerve. As a consequence of this microvascular pathology, diabetes is now the leading cause of new blindness in people aged 20–74 years, and the leading cause of end-stage renal disease. Diabetics are the fastest growing group of renal dialysis and transplant recipients. The life-expectancy for patients with diabetic end-stage renal failure is only 3 or 4 years. Over 60% of diabetics are affected by neuropathy, which includes distal symmetrical polyneuropathy, mononeuropathies, and a variety of autonomic neuropathies causing erectile dysfunction, urinary incontinence, gastroparesis, and nocturnal diarrhea. Life expectancy is about 7–10 years shorter than for people without diabetes.¹

Epidemiological studies show a strong relationship between glycemia and diabetic complications in both type 1 (T1DM) and type 2 (T2DM) diabetes mellitus.^{2,3} There is a continuous, though not linear, relationship between level of glycemia and the risk of development and progression of complications.^{4,5} This chapter integrates the vast amount of data about specific mechanisms by which hyperglycemia may damage diabetic blood vessels into a coherent, unified perspective. The discussion begins with the shared pathophysiologic features of microvascular complications, including the primacy of intracellular hyperglycemia, the development of microvascular complications during posthyperglycemic euglycemia (“hyperglycemic memory”) and the influence of genetic factors in determining susceptibility to microvascular complications. After discussing each known major mechanism of hyperglycemia-induced vascular damage, recent data are presented showing that these different pathogenic mechanisms all reflect a single hyperglycemia-induced process. The chapter concludes with a brief consideration of the prospects for mechanism-based pharmacologic intervention.

SHARED PATHOPHYSIOLOGIC FEATURES OF MICROVASCULAR COMPLICATIONS

In the retina, glomerulus, and vasa nervorum, diabetes-specific microvascular disease is characterized by similar pathophysiologic features.

Requirement for Intracellular Hyperglycemia

Clinical and animal model data indicate that chronic hyperglycemia is the central initiating factor for all types of diabetic microvascular disease. Duration and magnitude of hyperglycemia are both strongly correlated with the extent and rate of progression of diabetic microvascular disease. In the Diabetes Control and Complications Trial (DCCT), for example, T1DM patients whose intensive insulin therapy resulted in HbA_{1c} levels 2% lower than those receiving conventional insulin therapy had a 76% lower incidence of retinopathy, a 54% lower incidence of nephropathy, and a 60% reduction in neuropathy.^{2,3}

Although all diabetic cells are exposed to elevated levels of plasma glucose, hyperglycemic damage is limited to those cell types, such as endothelial cells, that develop intracellular hyperglycemia. Endothelial cells develop intracellular hyperglycemia because, unlike many other cells, they are unable to downregulate glucose transport when exposed to extracellular hyperglycemia. As illustrated in Fig. 13-1, vascular smooth muscle cells, which are not damaged by hyperglycemia, show an inverse relationship between extracellular glucose concentration and subsequent rate of glucose transport, measured as 2-deoxyglucose uptake. In contrast, vascular endothelial cells show no significant change in subsequent rate of glucose transport after exposure to elevated glucose concentrations.⁶ That intracellular hyperglycemia is necessary and sufficient for the development of diabetic pathology is demonstrated by the fact that overexpression of the GLUT-1 glucose transporter in mesangial cells cultured in a normal glucose milieu mimics the diabetic phenotype, inducing the same increases in collagen type IV, collagen type I, and fibronectin gene expression as diabetic hyperglycemia (Fig. 13-2).⁷

Abnormal Endothelial Cell Function

Early in the course of diabetes, before structural changes are evident, hyperglycemia causes abnormalities in blood flow and vascular permeability in the retina, glomerulus, and peripheral nerve vasa nervorum.^{8,9} The increase in blood flow and intracapillary pressure is thought to reflect hyperglycemia-induced decreased nitric oxide production on the efferent side of capillary beds, and possibly an increased sensitivity to angiotensin II. As a consequence of increased intracapillary pressure and endothelial cell dysfunction, retinal capillaries exhibit increased leakage of fluorescein and glomerular capillaries have an elevated albumin excretion rate. Comparable changes occur in the vasa vasorum of peripheral

nerve. Early in the course of diabetes, increased permeability is reversible, but as time progresses, it becomes irreversible.

Increased Vessel Wall Protein Accumulation

The common pathophysiologic feature of diabetic microvascular disease is progressive narrowing and eventual occlusion of vascular lumina, which results in inadequate perfusion and function of the affected tissues. Early hyperglycemia-induced microvascular hypertension and increased vascular permeability contribute to irreversible microvessel occlusion by three processes. The first is an abnormal leakage of periodic acid-Schiff (PAS)-positive, carbohydrate-containing plasma proteins, which are deposited in the capillary wall and may stimulate perivascular cells such as pericytes and mesangial cells to elaborate growth factors and extracellular matrix. The second is extravasation of growth factors such as transforming growth factor ($TGF\beta_1$), which directly stimulate overproduction of extracellular matrix components.¹⁰ The third pathologic process is hypertension-induced stimulation of pathologic gene expression by endothelial cells and supporting cells, which include growth factors, growth factor receptors, extracellular matrix components, and adhesion molecules that can activate circulating leukocytes.¹¹ The observation that unilateral reduction in the severity of diabetic microvascular disease occurs on the side with ophthalmic or renal artery stenosis is consistent with this concept.^{12,13}

Microvascular Cell Loss and Vessel Occlusion

The progressive narrowing and occlusion of diabetic microvascular lumina is also accompanied by microvascular cell loss. In the retina, diabetes induces programmed cell death of Muller

cells/ganglion cells,¹⁴ pericytes, and endothelial cells.¹⁵ In the glomerulus, declining renal function is associated with widespread capillary occlusion, but the mechanisms underlying glomerular endothelial cell loss are not yet known. In the vasa nervorum, endothelial cell and pericyte degeneration occur,¹⁶ and these microvascular changes appear to precede the development of diabetic peripheral neuropathy.¹⁷ The multifocal distribution of axonal degeneration in diabetes supports a causal role for microvascular occlusion, but hyperglycemia-induced decreases in neurotrophins may contribute by preventing normal axonal repair and regeneration.¹⁸

Development of Microvascular Complications During Posthyperglycemic Euglycemia (Hyperglycemic Memory)

Another common feature of diabetic microvascular disease has been termed *hyperglycemic memory*. This refers to the persistence or progression of hyperglycemia-induced microvascular alterations during subsequent periods of normal glucose homeostasis. The most striking example of this phenomenon is the development of severe retinopathy in histologically normal eyes of diabetic dogs, which occurred entirely during a 2.5-year period of normalized blood glucose that followed 2.5 years of hyperglycemia (Fig. 13-3).¹⁹ Normal dogs were compared to diabetic dogs with either poor control for 5 years, good control for 5 years, or poor control for 2.5 years ($P \rightarrow G_a$) followed by good control for the next 2.5 years ($P \rightarrow G_b$). HbA_{1c} values for both the good control group and the $P \rightarrow G_b$ group were identical to the normal group. Hyperglycemia-induced increases in selected matrix gene transcription also persist for weeks after restoration of normoglycemia *in vivo*, and a less pronounced, but qualitatively similar, prolongation of hyperglycemia-induced increase in selected matrix gene transcription occurs in cultured endothelial cells.²⁰

Data from the DCCT study suggest that hyperglycemic memory occurs in patients. In the secondary intervention cohort, there was no difference in the incidence of sustained progression of retinopathy for the first 3 years, no difference in development of clinical albuminuria for 4 years, and no difference in the rate of change in creatinine clearance during the entire study. For neuropathy, the sural nerve sensory conduction velocity did not differ between the groups for 4 years, and intensive therapy did not slow the rate of decline of autonomic function at all.^{2,21-23} Even more strikingly, the effects of former intensive and conventional therapy on the occurrence and severity of retinopathy and nephropathy were shown to persist for 4 years after the DCCT, despite nearly identical glycosylated hemoglobin values during the four-year follow-up (8.2% vs. 7.9%, respectively).²⁴ Taken together, these observations from animal and clinical studies imply that hyperglycemia induces prolonged and sometimes irreversible changes in long-lived intracellular molecules that persist and cause continued pathologic function in the absence of continued hyperglycemia.

Genetic Determinants of Susceptibility to Microvascular Complications

Clinicians have long observed that different patients with similar duration and degree of hyperglycemia could differ markedly in their susceptibility to microvascular complications. Such observations suggested that genetic differences existed that affected the pathways by which hyperglycemia damaged microvascular cells.

FIGURE 13-2. Overexpression of GLUT-1 in mesangial cells cultured in normal glucose mimics the diabetic phenotype. Mesangial cells transfected with either LacZ (**MCLacZ**) or GLUT-1-expressing constructs (**MCGTI**) were cultured in 5 mmol glucose and the amount of the indicated matrix components secreted was determined. (Reproduced with permission from Heilig et al.⁷)

The leveling of risk of overt proteinuria after 30 years' duration of type 1 diabetes at 27% is evidence that only a subset of patients are susceptible to developing diabetic nephropathy.²⁵ A role for genetic determinant of susceptibility to diabetic nephropathy is most strongly supported by the demonstration of familial clustering of diabetic nephropathy. In two studies of families with two or more siblings having type 1 diabetes, if one diabetic sibling has advanced diabetic nephropathy, the other diabetic sibling has a nephropathy risk of 83% or 72%, while the risk is only 17% or 22% if the index case does not have diabetic nephropathy (Fig. 13-4).^{26,27} For retinopathy, the DCCT reported familial clustering as well, with an odds ratio of 5.4 for the risk of severe retinopathy in diabetic relatives of positive versus negative subjects from the conventional treatment group.²⁸ Numerous associations have been made between various genetic polymorphisms and the risk of developing various diabetic complications. Examples include the 5' insulin gene polymorphism,²⁹ the G2m (23+) immunoglobulin allotype,³⁰ angiotensin-converting enzyme insertion/deletion polymorphisms,^{31,32} HLA-DQB1*0201/0302 alleles,³³ polymorphisms of the aldose reductase gene,³⁴ and a polymorphic CCTTT (n) repeat of nitric oxide synthetase 2A.³⁵ In all of these studies, there is no indication that the polymorphic gene actually plays a functional

role, rather than simply being in linkage disequilibrium with the locus encoding the unidentified relevant gene(s).

MECHANISMS OF HYPERGLYCEMIA-INDUCED DAMAGE

Four major hypotheses about how hyperglycemia causes diabetic complications have generated a large amount of data, as well as several clinical trials based on specific inhibitors of these mechanisms. Until quite recently, there was no unifying hypothesis linking these four mechanisms together, nor was there an obvious connection between any of these mechanisms, each of which responds quickly to normalization of hyperglycemia, and the phenomenon of hyperglycemic memory (discussed above).

Increased Polyol Pathway Flux

Aldose Reductase Function

Aldose reductase [alditol:NAD(P)⁺ 1-oxidoreductase, EC 1.1.1.21] is a cytosolic, monomeric oxidoreductase that catalyzes the NADPH-dependent reduction of a wide variety of carbonyl

FIGURE 13-3. Development of retinopathy during post-hyperglycemic normoglycemia ("hyperglycemic memory"). Quantitation of retinal microaneurysms and acellular capillaries in normal dogs, dogs with poor glycemic control for 5 years, dogs with good glycemic control for 5 years, dogs with poor glycemic control for 2.5 years ($P \rightarrow G_a$) and the same dogs after a subsequent 2.5 years of good glycemic control ($P \rightarrow G_b$) (Reproduced with permission from Engerman et al.¹⁹)

FIGURE 13-4. Familial clustering of diabetic nephropathy. Prevalence of diabetic nephropathy in two studies of diabetic siblings of probands with or without diabetic nephropathy.

FIGURE 13-5. Aldose reductase function and the polyol pathway. Aldose reductase reduces reactive oxygen species (ROS)-generated toxic aldehydes to inactive alcohols, and glucose to sorbitol, using NADPH as a cofactor. Sorbitol dehydrogenase (SDH) oxidizes sorbitol to fructose using NAD^+ as a cofactor (see text for details). Aldose reductase may be activated by ROS-induced reduction of nitric oxide modification of a cysteine residue in the enzyme's active site (*Reproduced with permission from Brownlee.*¹⁷⁵)

compounds including glucose. Aldose reductase converts a variety of toxic aldehydes (such as 2-oxo-aldehydes and those derived from lipid peroxidation) to inactive alcohols. NADPH is the cofactor in both this reaction and in the regeneration of glutathione by glutathione reductase. Aldose reductase has a low affinity (high K_m) for glucose, and at the normal glucose concentrations found in nondiabetics, metabolism of glucose by this pathway constitutes a very small percentage of total glucose utilization. However, in a hyperglycemic environment, increased intracellular glucose concentration (and possibly oxidant stress-induced aldose reductase activation) results in increased enzymatic conversion to the polyalcohol sorbitol, with concomitant decreases in NADPH. In cells having aldose reductase activity that is sufficient to deplete the endogenous antioxidant glutathione, hyperglycemia-induced oxidative stress would be augmented. In the polyol pathway, sorbitol is oxidized to fructose by the enzyme sorbitol dehydrogenase (SDH), with NAD^+ reduced to NADH (Fig. 13-5).

Biochemical Consequences of Increased Polyol Pathway Flux

A number of mechanisms have been proposed to explain the potential detrimental effects of hyperglycemia-induced increases in polyol pathway flux. These include sorbitol-induced osmotic stress, decreased Na^+/K^+ -ATPase activity, increased cytosolic NADH/ NAD^+ , and decreased cytosolic NADPH. Sorbitol does not diffuse easily across cell membranes, and it was originally suggested that this resulted in osmotic damage to microvascular cells. However, sorbitol concentrations measured in diabetic vessels and nerves are far too low to cause osmotic damage.

Another early suggestion was that increased flux through the polyol pathway decreased Na^+/K^+ -ATPase activity. Although this was originally thought to be mediated by polyol-pathway-linked decreases in phosphatidylinositol synthesis, it has recently been shown to result from activation of protein kinase C (PKC; see below). Hyperglycemia-induced activation of PKC increases cytosolic phospholipase A_2 activity, which increases the production of two inhibitors of Na^+/K^+ -ATPase, arachidonate and PGE_2 .³⁶

More recently, it has been proposed that oxidation of sorbitol by NAD^+ increases the cytosolic ratio of NADH to NAD^+ , thereby in-

hibiting activity of the enzyme glyceraldehyde-3-phosphate dehydrogenase, and increasing concentrations of triose phosphate.³⁷ Elevated triose phosphate concentrations could increase formation of both methylglyoxal, a precursor of advanced glycation endproducts, and diacylglycerol (via α -glycerol-3-phosphate), thus activating PKC (discussed in subsequent sections). Although increased NADH production is supported by the observation that hyperglycemia increases both lactate concentration and the lactate:pyruvate ratio, there is no direct evidence that the concentrations of NADH and NAD^+ , as opposed to NADH and NAD^+ flux, are altered. In endothelial cells, where aldose reductase activity is low, increased NADH production may also reflect hyperglycemia-induced increased flux through glycolysis³⁸ and through the glucuronic acid pathway.³⁹

Other evidence presented in support of this hypothesis includes the observation that administration of pyruvate can prevent diabetes-related endothelial dysfunction in some systems. However, the observed effects of pyruvate on microvascular function may reflect its potent antioxidant properties rather than effects on the NADH: NAD^+ ratio, since reactive oxygen species also partially inhibit glyceraldehyde-3-phosphate dehydrogenase and increase glyceraldehyde-3-phosphate levels.^{40,41} The source of hyperglycemia-induced reactive oxygen species will be discussed later in this chapter.

It has also been proposed that reduction of glucose to sorbitol by NADPH consumes the cofactor NADPH. Since NADPH is required for regenerating reduced glutathione (GSH), this could induce or exacerbate intracellular oxidative stress. Less reduced GSH has in fact been found in the lenses of transgenic mice that overexpress aldose reductase, and this is the most likely mechanism by which increased flux through the polyol pathway has deleterious consequences.⁴² Hyperglycemia-induced inhibition of glucose-6-phosphate dehydrogenase, the major source of NADPH regeneration, may further reduce NADPH concentration in some diabetic microvascular cells.⁴³

Increased Intracellular AGE Formation

Advanced Glycation Endproducts Form from Intracellular Dicarbonyl Precursors

Advanced glycation endproducts (AGEs) are found in increased amounts in extracellular structures of diabetic retinal vessels⁴⁴⁻⁴⁶ and renal glomeruli,⁴⁷⁻⁴⁹ where they can cause damage by mechanisms described later in this section. These AGEs were originally thought to arise from nonenzymatic reactions between extracellular proteins and glucose. However, the rate of AGE formation from glucose is orders of magnitude slower than the rate of AGE formation from glucose-derived dicarbonyl precursors generated intracellularly, and it now seems likely that intracellular hyperglycemia is the primary initiating event in the formation of both intracellular and extracellular AGEs.⁵⁰ AGEs can arise from intracellular autooxidation of glucose to glyoxal,⁵¹ decomposition of the Amadori product to 3-deoxyglucosone (perhaps accelerated by an Amadoriase), and fragmentation of glyceraldehyde-3-phosphate to methylglyoxal⁵² (Fig. 13-6). These reactive intracellular dicarbonyls react with amino groups of intracellular and extracellular proteins to form AGEs. Methylglyoxal and glyoxal are detoxified by the glyoxalase system.⁵² All three AGE precursors are also substrates for other reductases.^{53,54}

Intracellular production of AGE precursors damages target cells by three general mechanisms (Fig. 13-7). First, intracellular

FIGURE 13-6. Intracellular AGE formation. Potential pathways leading to the formation of advanced glycation endproducts (AGEs) inside cells (see text for details). (Reproduced with permission from Shinohara et al.⁵⁷)

proteins modified by AGEs have altered function. Second, extracellular matrix components modified by AGE precursors interact abnormally with other matrix components and with matrix receptors (integrins) on cells. Third, plasma proteins modified by AGE precursors bind to AGE receptors on cells such as macrophages, inducing receptor-mediated reactive oxygen species production. This AGE receptor ligation activates the pleiotrophic transcription factor NF κ B, causing pathologic changes in gene expression.⁵⁵

FIGURE 13-7. Intracellular production of AGE precursors damages cells by three mechanisms. (Reproduced with permission from Brownlee.¹⁷⁶)

Advanced Glycation Endproducts Alter Intracellular Protein Function

In endothelial cells, intracellular AGE formation occurs very quickly. Within 1 week, AGE content increases 13.8-fold in endothelial cells cultured in media containing high levels of glucose.⁵⁶ Basic fibroblast growth factor (bFGF) is one of the major AGE-modified proteins in endothelial cells.⁵⁶ Endothelial cell cytosol mitogenic activity is reduced 70% by AGE formation when cytosolic AGE-bFGF is increased 6.1-fold. Proteins involved in macromolecular endocytosis are also modified by AGEs, since the 2.2-fold increase in endocytosis induced by hyperglycemia is also prevented by overexpression of the methylglyoxal-detoxifying glyoxalase I.⁵⁷ Glyoxalase-I overexpression also completely prevents the fourfold hyperglycemia-induced increase in Muller cell expression of angiopoietin-2, a factor that has been implicated in both pericyte loss and capillary regression.⁵⁸⁻⁶⁰ This observation suggests that the α -oxoaldehyde AGE precursors methylglyoxal and glyoxal modify transcriptional complex proteins and thereby activate gene expression.

Advanced Glycation Endproducts Interfere with Normal Matrix-Matrix and Matrix-Cell Interactions

AGE formation alters the functional properties of several important matrix molecules. Collagen was the first matrix protein used to demonstrate that glucose-derived AGEs form covalent, intermolecular bonds. This process is partly mediated by H₂O₂ production.^{61,62} On type I collagen, this crosslinking induces an expansion of the molecular packing.⁶³ These AGE-induced crosslinks alter the function of intact vessels. For example, AGEs decrease elasticity in large vessels from diabetic rats, even after vascular tone is abolished, and increase fluid filtration across the carotid artery.⁶⁴ AGE formation on type IV collagen from basement membrane inhibits lateral association of these molecules into a normal network-like structure by interfering with binding of the noncollagenous NC1 domain to the helix-rich domain.⁶⁵ AGE formation on laminin causes decreased polymer self-assembly, decreased binding to type IV collagen, and decreased binding of heparan sulfate proteoglycan.⁶⁶ *In vitro* AGE formation on intact glomerular basement membrane increases its permeability to albumin in a manner that resembles the abnormal permeability of diabetic nephropathy.^{67,68}

AGE formation on extracellular matrix not only interferes with matrix-matrix interactions, it interferes with matrix-cell interactions as well. For example, AGE modification of type IV collagen's cell-binding domains decrease endothelial cell adhesion,⁶⁹ and AGE modification of a six-amino-acid growth-promoting sequence in the A chain of the laminin molecule markedly reduces neurite outgrowth.⁷⁰ AGE modification of vitronectin reduced cell attachment-promoting activity.⁷¹

AGE Receptors Mediate Pathologic Changes in Gene Expression

Specific receptors for AGEs were first identified on monocytes and macrophages. Two AGE-binding proteins isolated from rat liver are both present on monocyte/macrophages. Antisera to either the 60-kd or 90-kd protein, recently identified as OST-48 and 80K-H, respectively,⁷² block AGE binding.⁷³ AGE protein binding to this receptor stimulates macrophage production of interleukin-1, insulin-like growth factor IGF-1, tumor necrosis factor α , transforming growth factor- β , macrophage colony-stimulating factor,

and granulocyte/macrophage colony-stimulating factor at levels that have been shown to increase glomerular synthesis of type IV collagen and to stimulate proliferation and chemotaxis of both arterial smooth muscle cells and macrophages.^{74–82} The macrophage scavenger receptor type 2 and galectin-3 have also been shown to recognize AGEs.^{83–86}

AGE receptors have also been identified on glomerular mesangial cells. *In vitro*, AGE protein binding to its receptor on mesangial cells stimulates platelet-derived growth factor secretion, which in turn mediates production of type IV collagen, laminin, and heparan sulfate proteoglycan.^{87,88}

Vascular endothelial cells also express AGE-specific receptors (RAGE). A 35-kd and a 46-kd AGE-binding protein have been purified to homogeneity from endothelial cells.^{89–91} The N-terminal sequence of the 35-kd protein was identical to lactoferrin, whereas the 46-kd protein was novel. A full-length, 1.5-kb cDNA for the 46-kd protein was cloned and sequenced. This novel AGE-binding protein appears to be a member of the immunoglobulin superfamily, with three disulfide-bonded immunoglobulin homology units. RAGE has been shown to mediate signal transduction via generation of reactive oxygen species, activation of NFκB, and p21 ras.^{92–94} AGE signaling is blocked in cells by expression of RAGE antisense cDNA⁹⁵ or antiRAGE ribozyme.⁹⁶

In endothelial cells, AGE binding to its receptor induces changes in gene expression that include alterations in thrombomodulin, tissue factor, and vascular cell adhesion molecule 1 (VCAM-1).^{97–100} These changes induce procoagulatory changes in the endothelial surface and increase the adhesion of inflammatory cells to the vessel wall. In addition, endothelial AGE receptor binding appears to mediate in part the hyperpermeability induced by diabetes, probably through the induction of vascular endothelial growth factor.^{101–103}

Activation of Protein Kinase C

Mechanism of Hyperglycemia-Induced Protein Kinase C Activation

Protein kinase Cs (PKCs) are a family of at least eleven isoforms, nine of which are activated by the lipid second messenger diacylglycerol (DAG). Intracellular hyperglycemia increases DAG content in cultured microvascular cells and in the retina and renal glomeruli of diabetic animals.^{104–106} Intracellular hyperglycemia appears to increase DAG content primarily by increasing its *de novo* synthesis from the glycolytic intermediate glyceraldehyde-3-phosphate *via* reduction to glycerol-3-phosphate and stepwise acylation.^{105,107} Increased *de novo* synthesis of DAG activates PKC both in cultured vascular cells^{106,108–110} and in retina and glomeruli of diabetic animals.^{106,108,105} Increased DAG primarily activates the β and δ isoforms of PKC, but increases in other isoforms have also been found, such as PKC-α and -ε isoforms in the retina and PKC-α and -δ in the glomerulus^{111,112} of diabetic rats.

Consequences of Hyperglycemia-Induced PKC Activation

In early experimental diabetes, activation of PKC-β isoforms has been shown to mediate retinal and renal blood flow abnormalities,¹¹³ perhaps by depressing nitric oxide production and/or increasing endothelin-1 activity (Fig. 13-8). Abnormal activation of PKC has been implicated in the decreased glomerular production of nitric oxide induced by experimental diabetes,¹¹⁴ and in the decreased smooth muscle cell nitric oxide production induced by hy-

FIGURE 13-8. Potential consequences of hyperglycemia-induced protein kinase C activation. Hyperglycemia increases diacylglycerol (DAG) content, which activates PKC, primarily the β and δ isoforms. Activated PKC has a number of pathogenic consequences which are described in the text. (Reproduced with permission from Koya et al.¹¹¹)

perglycemia.¹¹⁵ PKC activation also inhibits insulin-stimulated expression of eNOS mRNA in cultured endothelial cells.¹¹⁶ Hyperglycemia increases endothelin-1-stimulated mitogen-activated protein kinase (MAPK) activity in glomerular mesangial cells by activating PKC isoforms.¹¹⁷ However, the increased endothelial cell permeability induced by high glucose in cultured cells is mediated by activation of PKCα.¹¹⁸ Activation of PKC by elevated glucose also induces expression of the permeability-enhancing factor VEGF in smooth muscle cells.¹¹⁹

In addition to affecting hyperglycemia-induced abnormalities of blood flow and permeability, activation of PKC contributes to increased microvascular matrix protein accumulation by inducing expression of TGFβ₁, fibronectin, and α1(IV) collagen in both cultured mesangial cells^{120,121} and in glomeruli of diabetic rats.¹²² This effect appears to be mediated through PKC's inhibition of nitric oxide production.¹²³ However, hyperglycemia-induced expression of laminin C1 in cultured mesangial cells is independent of PKC activation.¹²⁴ Hyperglycemia-induced activation of PKC has also been implicated in the overexpression of the fibrinolytic inhibitor plasminogen activator inhibitor-1,¹²⁵ and in the activation of the pleiotropic transcription factor NFκB in cultured endothelial cells and vascular smooth muscle cells.^{126,127}

Increased Hexosamine Pathway Flux

A fourth hypothesis about how hyperglycemia causes diabetic complications has recently been formulated,^{128,129} in which glucose is shunted into the hexosamine pathway (Fig. 13-9). In this pathway, fructose-6-phosphate is diverted from glycolysis to provide substrates for reactions that require UDP-N-acetylglucosamine, such as proteoglycan synthesis and the formation of O-linked glycoproteins. Inhibition of the rate-limiting enzyme in the conversion of glucose to glucosamine, glutamine:fructose-6-phosphate amidotransferase (GFAT), blocks hyperglycemia-induced increases in the transcription of both transforming growth factor-α¹²⁸ and transforming growth factor-β₁ (TGF-β₁).¹²⁹ This pathway has previously been shown to play an important role in hyperglycemia-induced and fat-induced insulin resistance.^{130–132}

The mechanism by which increased flux through the hexosamine pathway mediates hyperglycemia-induced increases in gene transcription is not clear, but the observation that Sp1 sites reg-

FIGURE 13-9. Hyperglycemia increases hexosamine pathway flux. In this pathway, increased *O*-linked GlcNAc moieties on the transcription factor Sp1 increase its transactivating function and thus increase transcription of genes associated with diabetic complications. (Reproduced with permission from Kolm-Litry et al.¹²⁹)

ulate hyperglycemia-induced activation of the PAI-1 promoter in vascular smooth muscle cells¹³³ suggests that covalent modification of Sp1 by *N*-acetylglucosamine may explain the link between hexosamine pathway activation and hyperglycemia-induced changes in gene transcription. Virtually every RNA polymerase II transcription factor examined has been found to be *O*-GlcNAcylated,¹³⁴ and the glycosylated form of Sp1 appears to be more transcriptionally active than the deglycosylated form of the protein.¹³⁵ A fourfold increase in Sp1 *O*-GlcNAcylation caused by inhibition of the enzyme *O*-GlcNAc-β-*N*-acetylglucosaminidase resulted in a reciprocal 30% decrease in its level of serine/threonine phosphorylation, supporting the concept that *O*-GlcNAcylation and phosphorylation compete to modify the same sites on this protein.¹³⁶

GlcNAc modification of Sp1 may regulate other glucose-responsive genes in addition to TGFβ1 and PAI-1. Glucose-responsive transcription is regulated by Sp1 sites in the acetyl CoA carboxylase gene, the rate-limiting enzyme for fatty acid synthesis, for example, and it appears that posttranslational modification of Sp1 is responsible for this effect.^{137,138} Since virtually every RNA polymerase II transcription factor examined has been found to be *O*-GlcNAcylated,¹³⁴ it is possible that reciprocal modification by *O*-GlcNAcylation and phosphorylation of transcription factors other than Sp1 may function as a more generalized mechanism for regulating glucose-responsive gene transcription.

In addition to transcription factors, many other nuclear and cytoplasmic proteins are dynamically modified by *O*-GlcNAc moieties, and may exhibit reciprocal modification by phosphorylation in a manner analogous to Sp1.¹³⁴ Thus, activation of the hexosamine pathway by hyperglycemia may result in many changes in both gene expression and in protein function that together contribute to the pathogenesis of diabetic complications.

DIFFERENT PATHOGENIC MECHANISMS REFLECT A SINGLE HYPERGLYCEMIA-INDUCED PROCESS

Although specific inhibitors of aldose reductase activity, AGE formation, and PKC activation each ameliorate various diabetes-induced abnormalities in animal models, there has been no appar-

FIGURE 13-10. Glucose oxidation and the production of cytoplasmic and mitochondrial reducing equivalents.

ent common element linking the four mechanisms of hyperglycemia-induced damage discussed in the preceding section.^{139-142,113} It has also been conceptually difficult to explain the phenomenon of hyperglycemic memory (discussed in an earlier section) as a consequence of four processes that quickly normalize when euglycemia is restored. These issues may have now been resolved by the recent discovery that each of the four different pathogenic mechanisms could reflect a single hyperglycemia-induced process: overproduction of superoxide by the mitochondrial electron transport chain.^{38,143}

Hyperglycemia increases reactive oxygen species production inside cultured bovine aortic endothelial cells.¹⁴⁴ To understand how this occurs, a brief overview of glucose metabolism is helpful. Intracellular glucose oxidation begins with glycolysis in the cytoplasm, which generates NADH and pyruvate. Cytoplasmic NADH can donate reducing equivalents to the mitochondrial electron transport chain via two shuttle systems, or it can reduce pyruvate to lactate, which exits the cell to provide substrate for hepatic gluconeogenesis. Pyruvate can also be transported into the mitochondria, where it is oxidized by the tricarboxylic acid (TCA) cycle to produce CO₂, H₂O, four molecules of NADH, and one molecule of FADH₂. Mitochondrial NADH and FADH₂ provide energy for ATP production via oxidative phosphorylation by the electron transport chain (Fig. 13-10).

Electron flow through the mitochondrial electron transport chain is carried out by four inner membrane-associated enzyme complexes, plus cytochrome *c* and the mobile carrier ubiquinone.¹⁴⁵ NADH derived from both cytosolic glucose oxidation and mitochondrial TCA cycle activity donates electrons to NADH:ubiquinone oxidoreductase (complex I). Complex I ultimately transfers its electrons to ubiquinone. Ubiquinone can also be reduced by electrons donated from several FADH₂-containing dehydrogenases, including succinate:ubiquinone oxidoreductase (complex II) and glycerol-3-phosphate dehydrogenase. Electrons from reduced ubiquinone are then transferred to ubiquinol:cytochrome *c* oxidoreductase (complex III) by the ubisemiquinone radical-generating Q cycle.¹⁴⁶ Electron transport then proceeds through cytochrome *c*, cytochrome *c* oxidase (complex IV), and finally, molecular oxygen.

Electron transfer through Complexes I, III, and IV generates a proton gradient that drives ATP synthase (Complex V). When the electrochemical potential difference generated by this proton gradient is high, the life of superoxide-generating electron transport intermediates such as ubisemiquinone is prolonged. There appears to be a threshold value above which superoxide production is markedly increased (Fig. 13-11).¹⁴⁷

FIGURE 13-11. Production of superoxide by the mitochondrial electron transport chain. Increased hyperglycemia-derived substrate generates a high mitochondrial membrane potential ($\Delta\mu H^+$), which inhibits electron transport and increases the half-life of intermediates capable of reducing O_2 to superoxide (see text for details). (Reproduced with permission from Boss et al.¹⁷⁷)

Using inhibitors of both the shuttle that transfers cytosolic NADH into mitochondria, and the transporter that transfers cytosolic pyruvate into the mitochondria, the TCA cycle was shown to be the source of hyperglycemia-induced reactive oxygen species in endothelial cells. To determine the site of hyperglycemia-induced intracellular reactive oxygen species (ROS) production, endothelial cells were first incubated with either rotenone, an inhibitor of complex I, thenoyltrifluoroacetone (TTFA), an inhibitor of complex II, or carbonyl cyanide m-chlorophenylhydrazone (CCCP), an uncoupler of oxidative phosphorylation that abolishes the mitochondrial membrane proton gradient. Compared with baseline conditions (5 mmol glucose), incubation with 30 mmol glucose increased ROS production from 52.08 ± 1.03 (5 mmol glucose) to 154 ± 1.38 nmol/mL (Fig. 13-12). Rotenone did not reduce increased ROS production, while both TTFA and CCCP completely prevented the effect of hyperglycemia (Fig. 13-12).

Since pharmacologic inhibitors are not absolutely specific to one cellular target, experiments were also performed using molecular techniques. Overexpression of uncoupling protein-1 (UCP1), a specific protein uncoupler of oxidative phosphorylation capable of collapsing the proton electrochemical gradient,¹⁴⁸ also prevented the effect of hyperglycemia (Fig. 13-12). Antisense cDNA in the same gene transfer vector did not (Fig. 13-12). These results demonstrate that hyperglycemia-induced intracellular ROS are produced by the proton electrochemical gradient generated by the mitochondrial electron transport chain. Overexpression of manganese superoxide dismutase, the mitochondrial form of this antioxidant enzyme,¹⁴⁹ also prevented the effect of hyperglycemia (Fig. 13-12). This result demonstrates that superoxide is the reactive oxygen radical produced by this mechanism.

The effect of hyperglycemia-induced mitochondrial superoxide overproduction on polyol pathway flux was evaluated after first determining that sorbitol in these cells was exclusively derived from aldose reductase activity. Sorbitol levels were 2.6-fold higher than baseline (5 mmol glucose) when endothelial cells were incubated in 30 mmol glucose (Fig. 13-13). Hyperglycemia-induced sorbitol accumulation was completely prevented by TTFA, UCP1 and Mn-SOD (Fig. 13-13), indicating that mitochondrial superoxide overproduction stimulates aldose reductase activity. This obser-

FIGURE 13-12. Effect of agents that alter mitochondrial metabolism on hyperglycemia-induced reactive oxygen species (ROS) formation in bovine aortic endothelial cells. Cells were incubated in 5 mmol glucose, 30 mmol glucose alone, and 30 mmol glucose plus either rotenone, thenoyltrifluoroacetone (TTFA), carbonyl cyanide m-chlorophenylhydrazone (CCCP), antisense (AS), uncoupling protein-1 (UCP1), or manganese superoxide dismutase (Mn-SOD) HVJ-liposomes, and ROS were quantitated. FIGURE 13-13. Effect of agents that alter mitochondrial metabolism on hyperglycemia-induced sorbitol accumulation. Cells were incubated in 5 mmol glucose, 30 mmol glucose alone, and 30 mmol glucose plus either thenoyltrifluoroacetone (TTFA), antisense (AS), uncoupling protein-1 (UCP1), or manganese superoxide dismutase (Mn-SOD) HVJ-liposomes, as indicated. (Reproduced with permission from Nishikawa et al.³⁸)

vation is consistent with recent data suggesting that aldose reductase activity is reversibly downregulated by nitric oxide modification of a cysteine residue in the enzyme's active site,¹⁵⁰ and that reactive oxygen species appear to reduce nitric oxide levels in diabetic endothelium.¹⁵¹ It may also reflect the well-described reversible inhibition of glyceraldehyde-3-phosphate dehydrogenase by reactive oxygen species,^{41,143} which increases glyceraldehyde-3-phosphate levels and the levels of proximal glycolytic metabolites including glucose.

Next, the effect of hyperglycemia-induced mitochondrial superoxide overproduction on intracellular AGE formation was determined. In bovine aortic endothelial cells, hyperglycemia increases intracellular AGEs primarily, if not exclusively, by increasing the formation of AGE-forming methylglyoxal.⁵⁷ Therefore, the effect of TTFA, CCCP, UCP1, and Mn-SOD on hyperglycemia-induced formation of intracellular methylglyoxal-derived AGEs was examined (Fig. 13-14). Each of these agents completely prevented hyperglycemia-induced formation of intracellular AGEs (Fig. 13-14), indicating that mitochondrial superoxide initiates intracellular AGE formation. Since methylglyoxal is formed by fragmentation of glyceraldehyde-3-phosphate, this dependency on increased mitochondrial superoxide production also likely reflects increased glyceraldehyde-3-phosphate levels due to inhibition of

FIGURE 13-14. Effect of agents that alter mitochondrial metabolism on hyperglycemia-induced intracellular AGE formation. Cells were incubated in 5 mmol glucose, 30 mmol glucose alone, and 30 mmol glucose plus either thenoyltrifluoroacetone (TTFA), uncoupling protein-1 (UCP1), or manganese superoxide dismutase (Mn-SOD) HVJ-liposomes, as indicated. Age Densitometry (AU). (Reproduced with permission from Nishikawa et al.³⁸)

FIGURE 13-15. Effect of agents that alter mitochondrial metabolism on hyperglycemia-induced PKC activation. Cells were incubated in 5 mmol glucose, 30 mmol glucose alone, and 30 mmol glucose plus either thenoyltrifluoroacetone (TTFA), carbonyl cyanide m-chlorophenylhydrazine (CCCP), uncoupling protein-1 (UCP1), or manganese superoxide dismutase (Mn-SOD) HVJ-liposomes, as indicated, and PKC activity was determined in the membrane fraction. (Reproduced with permission from Nishikawa et al.³⁸)

glyceraldehyde-3-phosphate dehydrogenase by reactive oxygen species.^{41,143}

The effect of TTFA, CCCP, UCP1, and Mn-SOD on hyperglycemia-induced activation of PKC was also evaluated (Fig. 13-15). Each of these agents completely inhibited PKC activation, suggesting that mitochondrial superoxide overproduction initiates the hyperglycemia-induced *de novo* synthesis of diacylglycerol that activates PKC.¹⁵² Most likely this too reflects increased glyceraldehyde-3-phosphate levels due to inhibition of glyceraldehyde-3-phosphate dehydrogenase by reactive oxygen species.^{41,143}

Finally, the effect of hyperglycemia-induced mitochondrial superoxide overproduction on the hexosamine pathway was determined.¹⁴³ Hyperglycemia induced an increase in hexosamine pathway activity that was completely prevented by TTFA, CCCP, and by azaserine, an inhibitor of the rate-limiting enzyme in the hexosamine pathway (Fig. 13-16). The increased production of UDP-N-acetyl glucosamine by hyperglycemia-induced mitochondrial superoxide overproduction was shown to increase O-glycosylation of the transcription factor Sp1, which activated expression of genes known to contribute to the pathogenesis of diabetic complications.¹⁴³

FIGURE 13-16. Effect of agents that alter mitochondrial metabolism on hyperglycemia-induced hexosamine pathway activity. Cells were incubated in 5 mmol glucose, 30 mmol glucose alone, and 30 mmol glucose plus either thenoyltrifluoroacetone (TTFA), carbonyl cyanide m-chlorophenylhydrazine (CCCP), manganese (III) tetrakis(4-benzoic acid) porphyrin (TBAP), or azaserine as indicated, and UDP-GlcNAc concentration was determined.

FIGURE 13-17. Potential mechanism for initiating hyperglycemic memory. Hyperglycemia-induced increases in reactive oxygen species are generated as a consequence of increased reducing equivalents entering the mitochondrial electron transport chain. The increased ROS would not only increase aldose reductase activity, AGE formation, PKC activity, and hexosamine pathway activity, but would also induce mutations in mitochondrial DNA. (Reproduced with permission from Doctrow et al.¹⁷⁴)

Hyperglycemia-induced activation of the redox-sensitive pleiotrophic transcription factor NfκB was also prevented by inhibition of mitochondrial superoxide overproduction.³⁸

A POSSIBLE MOLECULAR BASIS FOR HYPERGLYCEMIC MEMORY

In contrast to the four known hyperglycemia-inducible abnormalities of intracellular metabolism, hyperglycemia-induced mitochondrial superoxide production may provide an explanation for the development of complications during posthyperglycemic normoglycemia (hyperglycemic memory). Hyperglycemia-induced increases in superoxide would not only increase aldose reductase activity, AGE formation, PKC activity, and hexosamine pathway activity, but may also induce mutations in mitochondrial DNA (Fig. 13-17).¹⁵³ Mitochondria are more vulnerable to mutation because mtDNA contains virtually no introns, lacks protective histones, and has no effective DNA repair mechanism.^{154–156} mtDNA has a 10- to 20-fold higher mutation rate than nuclear DNA.^{157,158} Defective electron transport complex subunits encoded by mutated mitochondrial DNA could eventually cause increased superoxide production at physiologic concentrations of glucose, with resultant continued activation of the four pathways despite the absence of hyperglycemia (Fig. 13-18).

PROSPECTS FOR PHARMACOLOGIC INTERVENTION

Aldose Reductase Inhibitors

In vivo studies of polyol pathway inhibition have yielded promising results with neuropathy but disappointing results in other target tissues of diabetic complications. During the course of a 5-year study, nerve conduction velocity progressively decreased in untreated diabetic dogs, while this decrease was prevented by treatment with an aldose reductase inhibitor (ARI).¹³⁹ Positive effects of ARIs on human diabetic neuropathy have been reported.^{159,160} In

FIGURE 13-18. Potential mechanism for sustaining hyperglycemic memory. Mitochondrial DNA mutated by hyperglycemia-induced ROS would encode defective electron transport chain subunits. These defective subunits would cause increased ROS production by the electron transport chain at physiologic concentrations of glucose and glucose-derived reducing equivalents, thus maintaining the activation of aldose reductase activity, AGE formation, PKC activity, and hexosamine pathway activity. (Reproduced with permission from Doctrow et al.¹⁷⁴)

contrast, aldose reductase inhibition failed to prevent retinopathy in a 5-year study in dogs, nor did it prevent capillary basement membrane thickening in the retina, kidney, or muscles.¹⁶¹ A 3-year human trial also failed to show any effect on diabetic retinopathy.¹⁶²

AGE Inhibitors

The hydrazine compound aminoguanidine was the first AGE inhibitor discovered,⁶² and its effect on diabetic pathology has been investigated in the retina, kidney, nerve, and artery. In the rat retina, diabetes causes a 19-fold increase in the number of acellular capillaries. Aminoguanidine treatment of diabetics prevented excess AGE accumulation and reduced the number of acellular capillaries by 80%. Diabetes-induced pericyte dropout also was markedly reduced by aminoguanidine treatments.⁴⁴

Similar results have been obtained in animal models of diabetic kidney disease.^{163–165} Diabetes increased AGEs in the renal glomerulus, and aminoguanidine treatment prevented this diabetes-induced increase. Untreated diabetic animals developed albuminuria that averaged 30 mg every 24 hours for 32 weeks. This was more than a 10-fold increase above control levels. In aminoguanidine-treated diabetic rats, the level of albumin excretion was reduced nearly 90%.³⁶ Untreated diabetic animals also developed the characteristic structural feature of human diabetic nephropathy, increased fractional mesangial volume. When diabetic animals were treated with aminoguanidine, the increase was completely prevented. A structurally unrelated AGE inhibitor, OPB-9195 also prevented the development and progression of experimental diabetic nephropathy by blocking type IV collagen overproduction and normalizing the expression of TGFβ.^{166,167}

In the peripheral nerve of diabetic rats, both motor nerve and sensory nerve conduction velocity are decreased after 8 weeks of diabetes.¹⁶⁸ Nerve action-potential amplitude is decreased by 37% and peripheral nerve blood flow is decreased by 57% after 24 weeks of diabetes.¹⁶⁹ Aminoguanidine treatment prevented each of these abnormalities of diabetic peripheral nerve function.^{168,169}

In a large randomized, double-blind, placebo-controlled, multicenter trial of aminoguanidine in type 1 diabetic patients with overt nephropathy, aminoguanidine lowered total urinary protein and slowed progression of nephropathy, over and above the effects of existing optimal care. In addition, aminoguanidine reduced the progression of diabetic retinopathy (defined as an increase by three or more steps in the ETDRS scale).^{170,171}

PKC Inhibitors

The recent development of a β isoform-specific PKC inhibitor has allowed *in vivo* studies to go forward, since the toxicity of nonselective PKC inhibitors precludes their use. LY333531 inhibits PKC β_1 and PKC β_2 with a half-maximal inhibitory constant (IC₅₀) that is at least 50-fold less than for other PKC isoforms.¹¹³ Treatment with LY333531 significantly reduced PKC activity in the retina and renal glomeruli of diabetic animals. Concomitantly, LY333531 treatment significantly reduced diabetes-induced increases in retinal mean circulation time, normalized diabetes-induced increases in glomerular filtration rate, and partially corrected urinary albumin excretion. Treatment of db/db mice with LY333531 for a longer period of time also ameliorated accelerated glomerular mesangial expansion.¹⁷² Clinical trials of LY333531 in human diabetic patients are currently in progress.

Hexosamine Pathway Inhibitors

To date, there have been no *in vivo* trials of hexosamine pathway inhibitors, but the *in vitro* data discussed earlier in this chapter suggest that inhibitors of the rate-limiting enzyme of this pathway, glutamine:fructose-6-phosphate amidotransferase (GFAT), would have beneficial effects.

Future Drug Targets

The recent discovery that each of the four different pathogenic mechanisms discussed in this chapter may reflect a single hyperglycemia-induced process^{38,143} suggests that interrupting the overproduction of superoxide by the mitochondrial electron transport chain could normalize polyol pathway flux, AGE formation, PKC activation, and hexosamine pathway flux, as well as a number of other hyperglycemia-induced mechanisms that remain to be discovered.

Novel compounds that act as superoxide dismutase/catalase mimetics already exist,^{173,174} and these compounds have been shown to normalize hyperglycemia-induced mitochondrial superoxide overproduction *in vitro*.¹⁴³ Compounds that directly prevent hyperglycemia-induced mitochondrial superoxide overproduction may also hold promise. Drugs that normalize superoxide-induced triose phosphate accumulation are another logical therapeutic strategy. These and the other agents described in this section may have unique clinical efficacy in preventing the development and progression of diabetic complications.

Molecular Mechanisms and Genetic Engineering of Insulin-Secreting Cells

Hindrik Mulder

Christopher B. Newgard

In the history of diabetes research, major breakthroughs in understanding of the molecular mechanisms underlying the two predominant forms of the disease have been rare, contributing to the slow development of new therapies. For example, the treatment for type 1 diabetes mellitus (T1DM) is much the same today as it was at the time of the discovery of insulin by Banting and Best in 1922. We also do not yet understand in detail the mechanism by which insulin-containing islet β cells are specifically destroyed by the immune system in T1DM, the mechanisms underlying development of β -cell dysfunction in the majority of patients with type 2 diabetes mellitus (T2DM), or the molecular and biochemical defects that cause insulin resistance.

The tools of molecular biology have been applied to diabetes research with increasing frequency and effectiveness over the past decade. In a preceding edition of this book, we wrote about the various gene transfer methods to help in understanding the mechanics of diabetes, both at the levels of insulin action and insulin secretion.¹ In the ensuing period, tremendous progress has been made, such that it is no longer possible to provide a complete overview of the entire field in a single chapter. For the current volume, we have therefore chosen to focus on new insights gained into the biology of the pancreatic islet β cell via genetic engineering and gene transfer experiments, paying particular attention to mechanisms of fuel-stimulated insulin secretion. We will begin with a brief general overview of gene transfer methods that are applicable to the study of islet β cells, and will close the chapter by discussing the potential use of genetically engineered cells for insulin replacement in diabetes.

OVERVIEW OF GENE TRANSFER METHODS

Strategies for introduction of foreign DNA into animal cells have evolved rapidly in the past two decades, such that today's scientist is confronted with a sometimes bewildering array of options. In our discussion of the application of gene transfer methods to β -cell research, three general approaches will be highlighted. The first is the use of physical or chemical methods to achieve alterations in the properties of cell membranes or of the DNA molecules to be transferred that allow DNA to penetrate an otherwise impermeable barrier. Examples of physicochemical transfection strategies include

(1) Ca_2PO_4 or DEAE-dextran-mediated transfer, in which these carriers form a complex with the DNA that results in efficient endocytosis and deposition of the DNA in the nucleus; (2) electroporation, or the application of brief high-voltage electric pulses to cells to create transient pores in the cell membrane that allow entry of DNA; and (3) lipid-mediated transfection in which liposomes or cationic lipids are mixed with DNA and assist in entry of DNA into the cell by fusion of the lipid complex with the cell membrane. In the field of islet β -cell biology, physical gene transfer methods have been used for transient transfection studies of isolated islets or β -cell lines. Since the efficiency of these methods is generally low they have been used mainly for evaluation of promoter function which requires introduction of genetic material into only a small subset of cells in a population. However, physical gene transfer methods can also be used for stable transfection, provided that the DNA to be transferred includes a selectable marker and the cell type under study is capable of sustained growth. By using vectors that contain different antibiotic resistance markers, or by use of single vectors containing multiple genes, it is possible to express multiple transgenes in a given cell. Stable transfection has become an important tool for working with β -cell lines, leading in several instances to creation of new lines with enhanced properties, as described later in this chapter.

The second strategy that will be considered is the creation of transgenic animals. This approach involves microinjection of DNA into the fertilized eggs of animals, usually mice, resulting in integration into the germline DNA. Once integrated, the new gene is replicated along with the chromosomal DNA, allowing for the dissemination of new genetic information in tissues of intact animals. More recently, a variant of this method has emerged, in which embryonic stem cells are transfected with DNA homologous to a chromosomal gene. The transfected DNA integrates into the genome by homologous recombination. This approach can be used for disrupting the chromosomal gene in cases in which the transfected DNA contains an insertion or mutation, or can be used to introduce a variant functional sequence. These methods for genetic manipulation represent powerful tools for modulating the expression of particular genes and assessing impact at the level of whole-organ function and whole-animal fuel homeostasis. In recent years, many examples of specific targeting of transgenes to the pancreatic islet β cell via constructs in which the insulin promoter is used to

direct gene expression have come to the fore, and several of these will be highlighted below.

The last approach to be discussed is the use of viral vectors. It has been appreciated for some time that viruses exist by virtue of their capacity to transfer genetic information into host cells. With the advent of recombinant DNA technology, this property of viruses has been exploited in the creation of a wide variety of gene transfer vectors. Much effort has been focused on vectors derived from retroviruses, particularly murine leukemia virus (MuLV), and a variety of packaging systems for propagation of recombinant retroviruses have been developed.^{2,3} RNA viruses are generally capable of reverse transcribing their genome to proviral DNA, which must be integrated into genomic DNA of mammalian cells in order to be expressed. This feature of retroviruses ensures permanent transfer of genetic information to target cells, but only under conditions in which cells are able to grow, since integration of the viral genome requires the presence of cellular factors that are only present during periods of DNA replication.³ Because pancreatic islets do not replicate efficiently *in vitro*, the MuLV class of retroviruses has had very limited application for gene transfer studies in β cells, except in cases in which islet growth is stimulated by culture in the presence of specific cell matrix components or growth factors.⁴

More recently, exciting new vector systems based on lentiviruses, an alternate class of retroviruses that includes human immunodeficiency virus (HIV), have been developed.⁵ Of particular importance is the fact that lentiviruses express two genes (*MA* and *Vpr*) that facilitate transport of viral DNA into the nucleus of nondividing cells, allowing viral integration in the absence of cell proliferation. A three-plasmid system for preparing recombinant lentiviruses has been developed, consisting of a modified HIV provirus packaging construct that contains defective genes for envelope proteins, a separate plasmid containing genes encoding MLV or VSV G envelope proteins, and a third plasmid known as a transducing vector that contains *cis*-acting sequences of HIV required for packaging, reverse transcription, and integration, as well as a cloning cassette for insertion of foreign genes.⁵ These vectors hold promise for stable gene transfer into cultured cells with low replicative activity, and several reports of lentivirus-mediated gene transfer to cultured pancreatic islets have appeared recently.^{6,7} While the use of the three-plasmid system and simian rather than human immunodeficiency virus sequences reduces concerns about safety with these vectors, there is still the potential for generation of replication-competent viruses via recombination with wild-type HIV. Recently, safer vectors have been described, in which just 22% of the HIV genome is included, involving none of the pathogenic sequences.^{8,9}

Given the limitations of RNA virus vectors, increasing attention has been paid to DNA viruses for gene transfer studies, in particular herpes simplex virus (HSV), adeno-associated virus (AAV), and adenovirus. HSV has a very large genome, and can accommodate more than 20 kb of insert DNA. However, this vector is largely used for gene transfer to cells of the nervous system, since natural infection by HSV involves invasion of neurons or sensory ganglia and establishment of a state of latency in those cell types.¹⁰

Recombinant adenovirus has a number of attractive features for metabolic applications. So-called first-generation adenovirus vectors are usually derived from human serotypes 2 or 5, and contain deletions in the E1A region, which controls expression of other early viral genes and is required for viral replication.^{11,12} Deletion of just the E1A region allows insert sizes of up to 4.8 kb, but larger inserts can be accommodated by deletion of the

nonessential E3 gene. Adenoviruses can be used to transduce a wide range of mammalian cells, including liver cells, islets of Langerhans, muscle cells, and cells of the central nervous system, independent of cell growth or replication. They can also be grown at remarkably high titers (in excess of 10^{12} plaque-forming units/mL) with minimal effort. Adenoviral vectors are the most efficient of all the viral vectors, with near 100% gene transfer commonly observed in cultured cells. Such high efficiency of gene transfer has been documented for several β -cell lines.^{13,14} Furthermore, as shown in Fig. 14-1, exposure of isolated rat islets to recombinant adenoviruses for short time periods (1–2 hours) allows transfer of genes to between 70% and 80% of islet cells.¹⁵ Importantly, insulin secretion is not affected by treatment of islets or insulin-secreting cell lines with recombinant adenoviruses containing irrelevant control genes (e.g., β -galactosidase). Finally, first generation recombinant adenoviruses are easily constructed, and new recombinant viruses can usually be produced in a time frame of 3–6 weeks. Readers interested in detailed methods for preparing first generation adenovirus vectors are referred to reference 16.

While recombinant adenovirus is clearly an excellent tool for high efficiency gene delivery to isolated islets and β -cell lines, it is not useful for gene transfer to islets in living animals. Systemic infusion of adenoviral vectors results in highly efficient and preferential gene transfer to liver.^{17–21} The preferential targeting of adenovirus-transferred genes to liver is probably explained by the sinusoidal vasculature of that organ, which allows direct contact of viral particles with hepatocytes, whereas transfer is limited in other tissues by vascular barriers. The pancreatic islets are perfused by an intense network of arterioles and venules, which contain small pores or fenestrations with a diameter of approximately 40 nm.²² Unfortunately, the adenovirus particle has a diameter of approximately 100 nm, making it too large to pass through the pores of the islet vasculature, even when animals are treated with dilating agents such as mannitol or histamine.²³

One potential alternative to adenovirus for *in vivo* delivery of genes to pancreatic islets is AAV, which is about one-tenth as large as adenovirus. AAV is also intriguing because it is known to integrate effectively into genomic DNA.²⁴ Unfortunately, AAV vectors that are currently available are limited to DNA inserts of 4.8 kb or less in size.²⁵ Furthermore, growth of AAV requires the presence of wild-type adenovirus (which must subsequently be removed from the viral preparation) or the use of packaging cell lines. This means that obtaining AAV stocks of high titer is both laborious and difficult. For all of these reasons, application of AAV to metabolic research in general and islet biology in particular has thus far been limited.

While lentiviral and adenoviral vectors are superb new tools for high efficiency gene delivery to isolated islets and β -cell lines, the only method available today for delivery of genes to the islets of intact animals is microinjection of constructs into fertilized eggs, primarily of mice. Thus an important goal for the field is the continued development of modified adenoviral, lentiviral, and AAV vectors, or other nonviral methods of gene transfer such as peptide/DNA conjugate approaches, for delivery of genes to the pancreatic islets *in vivo*. Development of such methods will be highly useful for studies of islet function in animal models other than mice, including disease models such as the Zucker diabetic fatty (ZDF) rat. The small size of the AAV viral particle relative to either HSV or adenovirus makes this vector potentially attractive for gene delivery to the pancreatic islets of Langerhans *in vivo*, and further work on this system is certainly warranted. Encouragement in this

INSIGHTS INTO MECHANISMS OF FUEL-STIMULATED INSULIN SECRETION GAINED FROM GENE TRANSFER STUDIES

General Mechanisms of Fuel-Stimulated Insulin Secretion

Pancreatic islet β cells secrete insulin in response to monomeric fuels such as glucose or fatty acids rather than large polymeric macromolecules such as glycogen or triglycerides. Important nutrient fuels include monosaccharides such as glucose; several L-amino acids such as glutamine, alanine, or leucine; long-chain fatty acids such as palmitate or oleate; or ketone bodies such as β -hydroxybutyrate or acetoacetate.

There is strong evidence in support of the view that nutrient stimulation of insulin secretion requires catabolism of the fuel in question. This is in contrast to the classical mechanism of signal transduction involving recognition of the structure of a stimulant or ligand by a specific receptor, and interaction of the occupied receptor with other molecules to produce second messengers. In the islet β cell, intermediary metabolism integrates the input from multiple fuel molecules to generate specific intermediates known as coupling factors, that link fuel metabolism with hormone secretion. These metabolic signaling systems can interact with classical ligand/receptor pathways. For example, glucose-stimulated insulin secretion is potentiated by glucagon-like peptide-1, which binds to a receptor related to the glucagon receptor, and by neurotransmitters such as acetylcholine, which transduce their signals via muscarinic receptors.²⁷ Interestingly, these receptor-mediated signaling ligands are ineffective as insulin secretagogues in the absence of a significant threshold of glucose metabolism.

FIGURE 14-2. Schematic summary of basic model of the biochemical mechanism of glucose-stimulated insulin secretion. Insulin secretion is coupled to glucose metabolism in islet β cells. Proposed coupling factors include a rise in the ATP:ADP ratio, with ATP being produced in the distal portion of glycolysis, (1) via NADH shuttles, (2) or via pyruvate oxidation, (3) The potential linkage of glucose and lipid metabolism in regulation of insulin release is also shown.

Among fuel secretagogues, glucose stands out because it is the only one that can stimulate insulin secretion independent of other fuels. In fact, all of the other nutrients mentioned require the presence of physiological glucose levels to be effective. It is therefore not surprising that glucose is the most well-studied β -cell secretagogue. Based on this work, a basic model of the mechanism by which glucose stimulates insulin secretion has evolved, and is shown in Fig. 14-2, although significant questions and areas of disagreement remain to be resolved.

The consensus basic model of the mechanism of glucose-stimulated insulin secretion (GSIS) links glucose metabolism to insulin secretion via modulation in ATP and ADP levels (see Chap. 4). The capacity of glucose to stimulate insulin secretion is directly linked to its transport into β cells and further metabolism to generate coupling factors. Entry of glucose into the β cell is achieved by facilitated glucose transporters known collectively as the GLUTs.²⁸ GLUT-2 has a higher K_m for glucose and capacity for glucose transport than other members of the family, and is the isoform that

is primarily expressed in rodent islets.^{29,30} Human islets also express GLUT-2, but at lower levels than rodent islets, and when isolated from cadaveric pancreata, they also express significant levels of the low- K_m glucose transporters GLUT-1 and GLUT-3.^{31,32} Upon entry of glucose into β cells, the sugar is phosphorylated to glucose-6-phosphate (G6P) by glucokinase, also known as hexokinase IV, which contributes more than 90% of the glucose phosphorylating capacity in this cell type.³³ Like GLUT-2, glucokinase is a member of a gene family (the hexokinases), and differs from other members in several functional aspects. Glucokinase has an $S_{0.5}$ for glucose of about 8 mM, sigmoidal substrate dependency (indicated by a Hill coefficient of 1.7), and unlike hexokinases I and II, is not allosterically inhibited by the product of its reaction, G6P.^{33,34} Thus, β cells are equipped with specialized proteins that mediate glucose transport and phosphorylation, and both proteins have kinetic features that allow them to regulate glucose metabolism in response to changes in the external glucose concentration.³⁵ Important new insights into the relative roles of glucose trans-

porters and glucose phosphorylating enzymes in regulation of glycolytic flux and GSIS have come from gene transfer experiments, as summarized below.

At physiological glucose concentrations, most of the G6P produced by the glucokinase reaction in β cells flows efficiently into glycolysis, with little storage in the form of glycogen or entry into the pentose monophosphate shunt.³³ An important coupling factor produced by glucose metabolism in the β cell is ATP, by one of three different pathways. First, a large fraction of the NADH produced in the glyceraldehyde phosphate dehydrogenase reaction can be transferred to the mitochondria for entry into the electron transport chain via the α -glycero-P and aspartate/malate shuttles. In keeping with this idea, the activity level of the mitochondrial glycero-P dehydrogenase is higher in islets than in any other cell type in which it has been measured.³⁶ Second, ATP is generated in the phosphoglycerokinase and pyruvate kinase reactions of glycolysis. Finally, ATP can be produced in mitochondria from oxidation of pyruvate. Only a small fraction of pyruvate is reduced to lactate in β cells, due to relatively low levels of lactate dehydrogenase.^{37–39}

As glucose levels rise and metabolism increases, there is a concomitant increase in the ATP:ADP ratio within β cells that signals that glucose is abundant. The increased ATP:ADP ratio stimulates insulin secretion in part by regulation of the conductance of adenine nucleotide-sensitive K^+ channels (K_{ATP} channels), with ATP serving as an inhibitor and ADP as an activator of the channel.^{40–42} Thus, as the ATP:ADP ratio is increased, the open state probability of these channels is decreased and the plasma membrane of the β cell becomes depolarized. Membrane depolarization opens voltage-sensitive Ca^{2+} channels, causing the cytosolic Ca^{2+} level to rise.⁴³

However, insulin secretion also seems to be regulated in a K_{ATP} channel-independent fashion. This became clear from experiments of Henquin and coworkers, who incubated islets with diazoxide and 30 mmol K^+ to render K_{ATP} channels insensitive to regulation by cellular ATP.⁴⁴ Under these conditions, glucose was still capable of stimulating insulin secretion, albeit not as effectively as in islets with normally-functioning channels. One interpretation of these results is that ATP is required for exocytosis of insulin-containing secretory granules, possibly at the level of providing energy for the movement of granules to the cell surface and fusion with the plasma membrane.

An intriguing and important issue that has emerged in the field of β -cell biology in recent years is the relevance of the interplay between glucose and lipid metabolism in regulation of insulin secretion. The long-chain acyl CoA (LC-CoA) hypothesis of stimulus-secretion coupling holds that part of the signal for insulin secretion that is generated by glucose catabolism is the production of cytosolic malonyl CoA, which is derived from citrate produced in the TCA cycle.⁴⁵ Malonyl CoA, in addition to being the proximal precursor of fatty acid biosynthesis, is an important regulatory molecule, in that increases in its levels cause inhibition of the mitochondrial enzyme carnitine palmitoyl transferase I (CPT I), which regulates entry of long-chain acyl CoAs into the mitochondria for oxidation.⁴⁶ Thus, increases in malonyl CoA secondary to increased glucose metabolism cause diversion of LC-CoA from oxidation to esterification pathways, and it has been proposed that increases in the levels of cytosolic LC-CoA esters are a key signal in GSIS.⁴⁵ Feasible sites at which increased LC-CoA could influence insulin secretion include conversion to bioactive metabolites such as diacylglycerol or inositol trisphosphate (IP_3),⁴⁷ contribution to plasma membrane or secretory granule membrane lipid turnover, or direct acylation of proteins involved in secretory granule trafficking.

Biochemical events that mediate insulin secretion distal to th glucose-induced increases in the phosphate potential and intracellular Ca^{2+} are not well understood. Potentially relevant is the activation of two types of protein kinases, protein kinase C (PKC) and Ca^{2+} -calmodulin dependent protein kinase (PKCaCM), during exposure of islets to stimulatory glucose. While it has been speculated that the role of PKCaCM or other Ca^{2+} -calmodulin-regulated kinases such as myosin light chain kinase may be to phosphorylate cytoskeletal or secretory granule proteins, thereby causing movement of granules within cells and exocytosis, definitive evidence for such a process is lacking.

Studies of synaptic vesicle exocytosis from nerve terminal may provide important insights into potential direct actions of Ca^{2+} and ATP on insulin granule exocytosis. Neurotransmitter release from synaptic vesicles involves a cascade of protein-protein interactions that mediate movement of the vesicles to the presynaptic plasma membrane, followed by docking, priming, fusion/exocytosis, and endocytosis of the vesicle.⁴⁸ The proteins involved in these processes are well characterized, and several are regulated by Ca^{2+} in either direct or indirect ways. Some of the proteins involved in synaptic vesicle exocytosis and neurotransmitter release have also been identified in insulin-producing cells in the pancreatic islets, including SNAP-25, vesicle-associated protein-2 (VAMP-2), and syntaxins 1A, 4, and 5.^{49,50} Others such as synaptobrevin have been localized in a small subset of islet endocrine cells. While it is likely that a subset of the proteins and factors involved in synaptic vesicle exocytosis will also be involved in regulation of insulin secretion, much more work will be required to fully elucidate the specific differences and similarities between the two systems, including islet gene transfer experiments.

To summarize the basic model, increases in circulating glucose concentration are "sensed" by the β cell via a proportional increase in glycolytic rate. Both GLUT-2 and glucokinase participate in translation of changes in glucose concentration to modification in insulin secretion via regulation of entry of glucose into glycolysis, with a dominant role being played by glucokinase, as discussed below. The activation of glycolysis increases the ATP:ADP ratio by generation of ATP at three sites: (1) the distal portion of glycolysis, (2) shuttling of reducing equivalents into the mitochondria and activation of the electron transport chain and oxidative phosphorylation, and (3) glucose oxidation. The increase in ATP:ADP ratio causes inhibition of K_{ATP} channels, resulting in membrane depolarization and Ca^{2+} influx. The rise in intracellular Ca^{2+} triggers insulin secretion by one or some combination of the mechanisms discussed above, or possibly by as yet undiscovered pathways. A fascinating aspect of the glucose signaling pathway is that it can be potentiated by several metabolic fuels, but these potentiating factors are unable to elicit a response in the absence of a minimal level of glucose. This suggests that fuels such as fatty acids, ketone bodies, or amino acids are unable to achieve a threshold of metabolically derived second messengers sufficient to stimulate insulin release.

Within this framework lie a number of fundamental and unanswered questions. First, among the several ways that ATP can be generated during active glucose metabolism, is any one more important or relevant than another? Second, is ATP produced as a result of glucose metabolism the only metabolic coupling signal, or are other events required? Third, what is the overall contribution of the K_{ATP} channel-independent pathway of insulin secretion, and how do specific metabolic fuels regulate this pathway? Finally, in addition to regulating insulin secretion in an acute fashion, glucose

also increases insulin gene expression and biosynthesis of the hormone. The effects of glucose on insulin synthesis, like those on secretion, appear to be mediated by glucose metabolism, but a number of lines of evidence suggest that the coupling factors may be different for the two effects. Thus the effects of glucose on insulin secretion are measured on a time scale of seconds, while glucose activation of insulin biosynthesis requires minutes to hours. Also, the threshold glucose concentration required for activation of insulin biosynthesis in islet β cells is considerably lower than that required for stimulation of insulin secretion.⁵¹

In short, while regulation of insulin secretion has been studied intensively for decades using biochemical and physiological tools, operative mechanisms are not yet fully understood. Recently, however, genetic engineering of islet cells has led to important new insights in this area. Key experiments of this type will now be reviewed.

Regulatory Roles of Glucose Transport and Phosphorylation in β Cells

A large number of gene transfer experiments have focused on the roles of GLUT-2 and glucokinase in regulation of GSIS. Interest in these molecules has been stimulated by the fact that their expression is impaired in diabetes.^{35,52} In humans, the important role of glucokinase in glucose sensing has been highlighted by the discovery that a subset of patients with maturity onset diabetes of the young (MODY) are heterozygous for mutations in the glucokinase gene.⁵³ These mutations render the enzyme less active, diminishing the glucose phosphorylating capacity of the β cells and elevating the threshold for insulin secretion.

Important insights into the role of glucose phosphorylation in regulation of insulin secretion have been gained both from studies in transgenic animals and in experiments on cultured cells *in vitro*. Transgenic methods have been used to investigate the impact of reduced expression of glucokinase in islets of animal models, with results that are generally consistent with findings in MODY patients with glucokinase mutations. Expression of a glucokinase-specific ribozyme under control of the insulin promoter in transgenic mice resulted in a 70% reduction in immunodetectable glucokinase protein and enzyme activity.⁵⁴ Insulin secretion was impaired in these animals, with a reduction in total insulin release and an increase in the threshold concentration of glucose required for initiating the response. Unlike MODY patients, however, the transgenic mice were normoglycemic. Somewhat different results were obtained in animals heterozygous for knockout of the glucokinase gene. Animals with specific targeting of exon 1 of the islet isoform of the enzyme exhibited a 52% reduction in islet glucokinase activity, mild fasting hyperglycemia, and an abnormal response to a glucose challenge, despite normal hepatic glucokinase activity.⁵⁵ Transgenic mice heterozygous for disruption of a segment of the glucokinase gene that affects gene expression in both the liver and islets of Langerhans had a 30–40% decrease in glucokinase activity in both tissues, significant reduction in GSIS, and mild hyperglycemia.^{56,57} Interestingly, animals homozygous for knockout of the glucokinase gene die prior to or shortly after birth.^{55–57} Further, homozygous knockout of the β -cell isoform of glucokinase, with retention of normal hepatic expression of the enzyme, is sufficient to cause the neonatal lethality.⁵⁷ Also, in animals homozygous for knockout of both hepatic and β -cell glucokinase expression, restoration of β -cell glucokinase restores viability.⁵⁶

The role of glucose phosphorylating enzymes in control of insulin secretion has also been studied by their overexpression in pancreatic islets and β -cell lines. A consistent observation from several laboratories is that overexpression of hexokinases with high affinity for glucose results in a left shift in the glucose dependence of insulin secretion and insulin gene expression. Thus, overexpression of hexokinase I in fetal islets results in a sharp reduction in the concentration threshold for glucose activation of a cotransfected insulin promoter/chloramphenicol acetyl transferase (CAT) plasmid.⁵⁸ Similarly, overexpression of low- K_m yeast hexokinase in β cells of transgenic mice results in a left-shifted glucose response and an increase in total insulin output.⁵⁹ Treatment of freshly isolated rat islets with a recombinant virus containing the hexokinase I cDNA resulted in a doubling of insulin secretion from islets perfused at a nonstimulatory glucose concentration (3 mM), consistent with a 2.5- to 4-fold increase in 5-³H glucose usage and lactate production at this glucose concentration relative to the control groups.¹⁵ Finally, stable overexpression of hexokinase I in the MIN-6 insulinoma cell line resulted in a threefold enhancement of insulin secretion and glucose usage at low glucose levels.⁶⁰

Surprisingly, in contrast to the results obtained with overexpression of low- K_m hexokinases, overexpression of glucokinase in isolated rat islets or INS-1 insulinoma cells resulted in a substantial increase in glycolytic flux at low but not high glucose concentrations.^{39,61} In contrast, overexpression of glucokinase in hepatoma cell lines,⁶² isolated hepatocytes,^{39,63} or primary human myocytes⁶⁴ caused large increases in glycolytic flux and glycogen accumulation, even at glucose concentrations well above 5 mM. A detailed comparison of INS-1 cells and hepatocytes led to the conclusion that a fundamental difference between hepatocytes and islet β cells is the limited capacity of the latter to metabolize glycolytic intermediates beyond the glyceraldehyde-3-phosphate dehydrogenase step.³⁹

The foregoing studies may help to explain the finding that culture of GK (+/–) islets at high glucose levels resulted in increased glucokinase expression and near normalization of impaired glucose-stimulated insulin secretion.⁶⁵ Culture of GK (+/+) islets at high glucose concentrations also increased glucokinase expression, but in these islets the increased GK activity was accompanied by increased basal insulin secretion and a loss of the normal incremental response to stimulatory glucose. These findings correlate well with the increase in glucose metabolism at low but not high glucose concentrations observed in glucokinase-overexpressing INS-1 cells.^{39,61}

In contrast to the consistent experimental support for a critical role for the glucose phosphorylation step in regulation of β -cell glucose sensing, significant controversy exists with regard to the role played by the glucose transporter GLUT-2. To summarize briefly, the following observations have been made that are consistent with the hypothesis:

1. GLUT-2 expression is reduced in concert with the loss of GSIS in a wide variety of rodent models of diabetes (reviewed in references 35 and 52). For example, in diabetes-prone male Zucker diabetic fatty (ZDF) rats, but not in diabetes-resistant female ZDF animals, β -cell GLUT-2 levels decline in inverse proportion to the severity of hyperglycemia. At onset of diabetes, GLUT-2 is detectable in only 60% of the β -cells, and then continues to decline to undetectable levels.^{66,67} Similar observations have now been documented in the *db/db* mouse,⁶⁸ the GK rat,^{69,70} the dexamethasone-treated Wistar and Zucker

- fatty female rat,⁷¹ and the streptozocin-treated rat.⁷²
2. GLUT-2 expression is lost in concert with loss of glucose-stimulated insulin secretion in islet transplantation experiments.⁶⁸ Thus, transplantation of islets from normal animals into diabetic *db/db* mice or animals rendered diabetic by streptozocin injection results in loss of GLUT-2 protein expression and glucose responsiveness of the graft, while conversely, transplantation of GLUT-2 deficient islets from diabetic *db/db* mice into normal mice results in restoration of GLUT-2 expression and glucose sensing.⁶⁸
 3. Reduced expression of GLUT-2 in β cells of transgenic animals results in impaired glucose sensing.^{73,74} Thus, expression of the GLUT-2 cDNA in antisense configuration in islet β cells of transgenic mice under control of the insulin promoter resulted in an 80% depletion of islet GLUT-2 protein.⁷³ These transgenic animals exhibited an approximate twofold increase in basal glucose concentrations and a markedly impaired response to an intraperitoneal glucose tolerance test. Consistent with these observations, circulating insulin levels were decreased by 32% in the transgenic animals, and GSIS from transgenic islets was also sharply impaired. More recently, homologous recombination techniques have been used to generate GLUT-2 knockout mice.⁷⁴ GLUT-2 $-/-$ animals are hyperglycemic, hypoinsulinemic, and die at 3 weeks of age. Analysis of islets isolated from young animals prior to death reveals that the first phase of insulin secretion in response to glucose is abolished, while a modest second phase response remains.⁷⁵ Restoration of GLUT-2 expression by lentivirus transduction of cultured islets from GLUT-2 $-/-$ mice restores the first phase of GSIS.⁷⁵ Furthermore, expression of GLUT-2 under control of the rat insulin promoter (RIP) restores normal viability and regulation of insulin secretion in GLUT-2 knockout mice.⁷⁶
 4. Stable expression of GLUT-2 in neuroendocrine or insulinoma cell lines confers GSIS in cells that are otherwise unresponsive to the sugar,^{13,77,78} while GLUT-1, a transporter isoform with higher affinity but lower capacity for glucose uptake than GLUT-2 appears unable to confer responsiveness.⁷⁸ Interestingly, in the GLUT-2 $-/-$ mice, GSIS was restored by transgenic expression of either GLUT-1 or GLUT-2.⁷⁶ The reasons for the different results obtained with GLUT-1 expression in the transgenic animal versus cell line studies are not known, but could be related to the very high levels of GLUT-1 expression reported in the former.

While the foregoing studies provide support for an important role for GLUT-2 in normal glucose sensing, other work argues that the transporter has little direct influence. Thus depletion of GLUT-2 associated with overexpression of the *H-ras* oncogene,⁷⁹ in response to culturing of islets *in vitro*,⁸⁰ or as a result of hypoglycemic perfusion of the pancreas⁸¹ does not abrogate GSIS. In addition to these experimental findings, there is an important conceptual issue concerning a rate-determining role for GLUT-2 in glucose sensing, which is that glucose transport capacity has been reported to exceed the rate of glycolytic flux in rodent β cells by as much as two orders of magnitude.³³

Another observation that seemingly reduces the probability of an important role for GLUT-2 is the finding that human islets express lower levels of the protein than do rat islets, and that human β cells may express other transporter isoforms such as GLUT-1 and GLUT-3 in addition to GLUT-2.^{31,32} Thus the ratio of GLUT-2 protein and mRNA in liver and islets is reversed in rats versus humans (rats have higher GLUT-2 expression in islets than in liver, while

humans have less).³² Consistent with this finding, the rate of 3-methyl glucose transport in human islets is only five times higher than the rate of glycolysis, compared to 50–100 times higher in rodent islets.³¹ Furthermore, the rate of glucose metabolism in human islets increases by approximately 75% with a change in glucose from 5 to 10 mM, in concert with the increase in glucokinase activity, while glucose uptake increases by only 30%.³¹ Nevertheless, the closer relationship of glucose transport capacity and glycolytic rate in human islets compared to rodent islets may suggest that the former cells could be more susceptible to functional impairment in response to decreased GLUT-2 expression. Consistent with this, a single patient with type 2 diabetes has been reported with a point mutation in the GLUT-2 gene (V197L) that renders the expressed mutant protein unable to transport glucose.⁸² This finding suggests that reduced GLUT-2 expression may be sufficient to cause diabetes, although the contribution of reduced GLUT-2 expression in β cells relative to other sites of expression of the gene, such as liver or gut, was not determined.

Taken together, the studies performed to date on the role of GLUT-2 and glucokinase in regulation of GSIS are most consistent with a dominant regulatory role of the glucose phosphorylation step, but with an important permissive role played by the glucose transporter. It appears that the functional attribute of GLUT-2 that is most important for its putative role in glucose sensing is its high capacity for glucose transport rather than its low affinity for the sugar. Thus, as a high-capacity glucose transporter, GLUT-2 ensures that the intracellular glucose concentration in the β cell closely mirrors that in the circulation. This function of GLUT-2 allows glucokinase to be the major determinant of the glycolytic rate in β cells in response to changes in the external glucose concentration. Factors that allow glucokinase to fulfill this role include its relatively low level of expression in β cells and its kinetic properties.

Use of Genetic Engineering to Identify Stimulus/Secretion Coupling Factors

There is wide agreement that glucose metabolism generates factors that couple the glucose stimulus to insulin secretion.^{33,83,84} In spite of this consensus, the exact nature of these coupling factors remains unresolved. For example, there is conflicting information with regard to the relative importance of discrete pathway segments involved in glucose metabolism. Thus some investigators have reported that inhibitors of glycolytic metabolism, but not enzymes involved in the TCA cycle, abolish GSIS.⁸⁵ In contrast, another line of research has shown that the TCA cycle intermediate methylsuccinate or succinate (the latter applied to permeabilized INS-1 cells) evokes insulin secretion.⁸⁶ Succinate is an anaplerotic substrate, and its addition to β cells causes both Ca^{2+} influx into mitochondria and hyperpolarization of the mitochondrial membrane. Thus the insulinotropic effect of succinate would appear to be independent of factors generated in the glycolytic pathway. Recently, it has been proposed that glutamate may be the specific coupling factor for insulin secretion derived from mitochondrial metabolism.⁸⁷ Data supporting this idea included a measured increase in glutamate content in INS-1 cells exposed to stimulatory glucose and potentiation of GSIS by addition of dimethylglutamate to INS-1 cells or glutamate to permeabilized INS-1 cells. It was further proposed that glutamate acts directly on the exocytotic machinery, based on experiments in which inhibitors of vesicular glutamate transporters inhibited insulin secretion. However, another recent paper presents evidence of GSIS independent of changes in

FIGURE 14-3. Engineering of glycerol-stimulated insulin secretion from perfused rat islets. Freshly isolated rat islets were treated with recombinant adenoviruses containing genes encoding glycerol kinase (AdCMV-GlpK) or, as a control, β -galactosidase (AdCMV- β GAL), and perfusion studies were conducted 48 hours after viral treatment. Islets were perfused at a flow rate of 0.8 mL/min and fractions were collected at 1-minute intervals for measurement of insulin secretion. The perfusate additions are noted at the bottom of the figure. Note that only AdCMV-GlpK-treated islets increased insulin secretion in response to the addition of 5 mM glycerol to the basal perfusate (containing 1 mM glucose), while both groups of islets responded to the combination of 5 mM glycerol and 20 mM glucose. Data represent the mean $\pm$ SEM for three independent groups of islets per viral treatment. (Data used, with permission, from Noel, et al.¹⁴)

glutamate concentration, leaving open the question of the relevance of this intermediate.⁸⁸

Genetic engineering experiments are helping to resolve the confusion caused by the seemingly conflicting data just summarized. One approach is to compare the metabolic fates of glucose with those of other simple carbohydrates in order to identify those metabolic intermediates that are truly important in regulation of insulin secretion. For example, the triose glycerol is not normally an insulin secretagogue, due to the absence of the first enzyme of its metabolism in the β cell, glycerol kinase. However, as illustrated in Fig. 14-3, adenovirus-mediated expression of glycerol kinase allows INS-1 cells or isolated islets to metabolize glycerol effectively and to respond to glucose as an insulin secretagogue.¹⁴ Comparison of the metabolic fates of glycerol and glucose in glycerol kinase-expressing cells revealed that glucose was oxidized more effectively than glycerol, such that the amount of glycerol oxidized at its maximally stimulatory concentration for insulin secretion was similar to that of glucose at a nonstimulatory concentration (3 mM) of the hexose (Fig. 14-4A). Instead, glycerol was oxidized effectively to lactate (Fig. 14-4B). These data suggest that the ability of carbohydrate secretagogues via pyruvate expression, resulting in metabolized entry into the TCA cycle is not required

for GSIS, and instead directs attention towards reducing equivalent shuttles, the distal portions of glycolysis, or other metabolic pathways.

Other experiments of this type have been conducted to probe the "pyruvate paradox" of β -cell signaling, which refers to the lack of effect of pyruvate as an insulin secretagogue when applied to pancreatic islets, despite its ability to be oxidized by such cells. This has been investigated by overexpression of the monocarboxylic acid transporter (MCT), which is responsible for transport of lactate and pyruvate across the plasma membrane, and the enzyme lactate dehydrogenase (LDH) in INS-1 cells and isolated rat islets.⁸⁹⁻⁹¹ In one study, overexpression of LDH in INS-1 cells had no effect on GSIS, but did confer insulin secretion in response to lactate, while MCT expression had no effect on either variable.⁸⁹ The same investigators found that MCT overexpression in isolated islets conferred pyruvate-stimulated insulin secretion, whereas lactate-stimulated insulin secretion required co-overexpression of MCT and LDH. The ability of lactate and pyruvate to stimulate insulin secretion was correlated with their rates of oxidation in the two cell preparations, but was also linked to reducing equivalent shuttles, since aminooxyacetate (AOA) blocked glucose- or lactate-induced insulin secretion in LDH + MCT-overexpressing INS-1

FIGURE 14-4. Comparison of the metabolic fates of glucose and glycerol in INS-1 cells engineered for glycerol kinase expression. **A.** Oxidation of varying concentrations of U-¹⁴C glycerol (**left**) and U-¹⁴C glucose (**right**) by INS-1 cells treated with a recombinant adenovirus containing the glycerol kinase gene (AdCMV-GlpK). Data are expressed as total nmol CO₂ produced/mg protein/h for each substrate. Note that CO₂ production at concentrations of glycerol that are maximally stimulatory for insulin secretion (2–5 mM) are similar to the CO₂ produced at a concentration of glucose that is nonstimulatory for insulin secretion (3 mM). **B.** Lactate produced at varying concentrations of glycerol (**left**) and glucose (**right**) from the same AdCMV-GlpK-treated INS-1 cells studied in part A. Note that more glycerol is converted to lactate than glucose, the inverse of the oxidation data. For both panels, data represent the mean $\pm$ SEM of three independent groups of experiments, each performed in triplicate. (Data used, with permission, from Noel, et al.¹⁴)

cells. In contrast to these findings, another group reported that stable expression of LDH in an alternative insulinoma cell line, MIN-6, resulted in significant impairment of GSIS.^{90,91} The authors suggested that the LDH-catalyzed conversion of lactate to pyruvate consumes NAD^+ , which is required in the glycolytic reaction catalyzed by glyceraldehyde-3-phosphate dehydrogenase. Consequently, the glycolytic rate would be attenuated and the generation of coupling factors from glycolysis abrogated, inhibiting GSIS.

To shed further light on these issues, transgenic mice have been generated that lack mitochondrial glycerol-3-phosphate dehydrogenase,⁹² which is rate-limiting in the glycerol phosphate shuttle. This shuttle, along with the malate-aspartate shuttle, transfers reducing equivalents in the form of NADH from the cytosol to the mitochondria. GSIS was found to be normal in mice lacking mitochondrial glycerol-3-phosphate dehydrogenase activity. However, co-blockade of the malate-aspartate shuttle with AOA in the mice lacking glycerol-3-phosphate dehydrogenase abolished GSIS, whereas the drug had no effect on insulin secretion in normal mice. Based on these data, the authors proposed a model in which NADH both from the cytosol, generated by glycolysis, and from the mitochondrion, derived from the TCA cycle, is required for normal stimulus-secretion coupling in β cells. However, a paradoxical finding is that both glucose usage and $\text{U-}^{14}\text{C}$ -glucose oxidation were unaffected by blockade of the two shuttles, despite an anticipated deficiency in regeneration of NAD for glycolysis.

Taken together, the foregoing studies suggest that oxidation of glucose in the TCA cycle is not the critical event in glucose sensing, since glycerol was a potent secretagogue despite its poor efficiency of oxidation, while glucose failed to stimulate insulin secretion in islets with blockade of shuttle activity, despite normal oxidation of $\text{U-}^{14}\text{C}$ glucose. These experiments, coupled with the fact that pyruvate and lactate are effective secretagogues when they are transported and metabolized effectively (e.g., when sufficient MCT and LDH are present), instead suggest that signaling is most closely coupled to redox state or to a mitochondrial pathway other than pyruvate dehydrogenase-catalyzed entry of carbon into the TCA cycle. Further studies will be required to gain full understanding of these points.

Manipulation of the Link Between Metabolism of Glucose and Lipids in β Cells

As reviewed above, glucose is a primary regulator of insulin secretion, but the β cell also serves as a more general thermostat for fuel metabolism. Indeed, secretion of insulin is stimulated not only by glucose but also by free fatty acids (FFA) and amino acids. This raises the possibility that some coupling factors that regulate insulin secretion may be common to multiple metabolic pathways. For more than a decade, malonyl CoA has been considered as a potential example of a coupling factor that integrates metabolic pathways for stimulation of insulin secretion.⁴⁵ The proposed regulatory role of malonyl CoA originated from the observation that this intermediate rises rapidly in response to stimulatory glucose in HIT-T15 and INS-1 insulinoma cells and in isolated rodent islets.⁹³ The glucose-induced rise in malonyl CoA coincides with inhibition of fatty acid oxidation and precedes the initiation of insulin secretion. Malonyl CoA is a known allosteric inhibitor of carnitine palmitoyl transferase I (CPT I), the enzyme that transports long-chain acyl CoA (LC-CoA) into the mitochondrion for subsequent β -oxidation.⁴⁶ The LC-CoA/malonyl CoA hypothesis also holds

that LC-CoA accumulates in the cytosol as a consequence of malonyl CoA-mediated inhibition of CPT I, and that the rise in LC-CoA promotes exocytosis of insulin-containing secretory granules.

A number of observations support this model. For instance, in the perfused rat pancreas, abrogation of the link between glucose and malonyl CoA formation by administration of hydroxycitrate, an inhibitor of citrate lyase, causes an increase in fatty acid oxidation and inhibition of GSIS.⁹⁴ Conversely, suppression of fatty acid oxidation with inhibitors of CPT I, such as etomoxir, enhances GSIS. These findings seemingly support a role for malonyl CoA and cytosolic LC-CoA in β -cell stimulus-secretion coupling, but they can also be interpreted differently. Thus, the glucose-induced rise in malonyl CoA is correlated with, but not necessarily causal for, insulin secretion, hydroxycitrate is a potentially toxic compound with pleiotropic effects, and CPT I inhibitors are modified fatty acids; fatty acids are known potentiators of GSIS.

Genetic engineering experiments have been devised to test the LC-CoA/malonyl CoA model. In one such study, a recombinant adenovirus was used to overexpress the goose isoform of malonyl CoA decarboxylase in INS-1 cells.⁹⁵ This maneuver significantly attenuated the glucose-induced rise in malonyl CoA and partially reversed glucose-induced inhibition of fatty acid oxidation. The reduction in malonyl CoA levels also impaired the incorporation of glucose and palmitate into cellular lipids. However, despite this perturbation of the link between metabolism of glucose and lipids, GSIS was unaffected. Moreover, addition of an inhibitor of LC-CoA synthetase, triacsin C, to INS-1 cells or intact rat islets impaired glucose incorporation into total cellular lipids and lowered total cellular LC-CoA levels by 50%, but with no effect on GSIS. Finally, in INS-1 cells engineered for glycerol-stimulated insulin secretion by expression of glycerol kinase, incubation of the cells with triacsin C blocked glycerol incorporation into cellular lipids, but did not impair insulin secretion.¹⁴

While the foregoing study seems to argue against the LC-CoA model of GSIS, it has been criticized at several levels.^{96,97} Concerns raised include: (1) The INS-1 cell line used for the work exhibited only a two- to fourfold stimulation of insulin secretion as glucose was raised from 3 to 15 mM, as opposed to freshly isolated rat islets, which can exhibit a 10- to 15-fold response; (2) It is unclear if the K_{ATP} channel-independent pathway of GSIS is operative in INS-1 cells. This pathway has been implicated as the site at which lipids regulate insulin granule exocytosis;^{97,98} (3) The goose malonyl CoA decarboxylase (MCD) cDNA used earlier had its N-terminal mitochondrial targeting sequence deleted, but contained an intact C-terminal SKL peroxisomal targeting motif, raising the possibility that a significant fraction of the overexpressed enzyme failed to localize to the cytosol.

These outstanding concerns have been addressed recently. One important advance has been the development of INS-1-derived cell lines (e.g., 832/13) with robust K_{ATP} -channel-dependent and -independent GSIS.⁹⁹ The INS-1 cell line was originally derived from radiation-induced rat insulinoma (RIN) cells,¹⁰⁰ and has been popular in the field because it secretes insulin in response to glucose concentrations in the physiological range. However, the magnitude of the response is far less than that seen in freshly isolated rat islets (two- to fourfold in INS-1 cells versus 10- to 15-fold in freshly isolated islets), and even the modest response found in early passage INS-1 cells seems to wane with time in tissue culture. To investigate whether this loss of responsiveness might be due to clonal heterogeneity, parental INS-1 cells were transfected with a plasmid containing the human proinsulin gene, resulting in isolation of

more than 60 independent clones.⁹⁹ After antibiotic selection and clonal expansion, 67% of the clones were found to be poorly responsive to glucose in terms of insulin secretion ($\leq$ twofold stimulation by 15 mM compared to 3 mM glucose), 17% of the clones were moderately responsive (two- to fivefold stimulation), and 16% were strongly responsive (5- to 13-fold stimulation). The differences in responsiveness among these three groups could not be ascribed to differences in insulin content.⁹⁹ More detailed study of one of the strongly responsive lines (832/13) revealed that its responsiveness was stable for prolonged periods of continuous tissue culture, and that the cells exhibit half-maximal stimulation of insulin secretion at 6 mM glucose. Furthermore, insulin secretion was enhanced by known potentiators of islet insulin secretion such as IBMX, FFA, and glucagon-like peptide-1 (GLP-1). GSIS was also potentiated by the sulfonyleurea tolbutamide, and abolished by diazoxide, demonstrating the operation of the ATP-sensitive K^+ -channel (K_{ATP}) in 832/13 cells. Moreover, when the K_{ATP} channel was bypassed by incubation of cells in depolarizing K^+ (35 mM), insulin secretion was more effectively stimulated by glucose in 832/13 cells than in parental INS-1 cells or the glucose-unresponsive clones.

In addition to the development of new INS-1-derived cell lines, the human MCD cDNA has been cloned,¹⁰¹ and mutant forms of the cDNA lacking the mitochondrial and peroxisomal localization sequences have been inserted into adenovirus vectors.¹⁰² With this cadre of improved reagents, the effect of MCD overexpression on GSIS has been reexamined, again with the finding of no impairment of robust GSIS in 832/13 cells, despite complete blockade of the glucose-induced rise in malonyl CoA level (Fig. 14-5A).¹⁰² Furthermore, combined treatment of 832/13 cells with an adenovirus containing the modified human MCD cDNA and triacsin C did not impair GSIS (Fig. 14-5B). Interestingly, these maneuvers also did not affect potentiation of GSIS by fatty acids.

The LC-CoA model has also been investigated via modulation of the activity of acetyl CoA carboxylase (ACC), the enzyme that catalyzes malonyl CoA synthesis from acetyl CoA. In one approach, expression of acetyl CoA carboxylase was lowered by stable expression of an ACC-specific antisense construct in parental INS-1 cells.¹⁰³ The decrease in acetyl CoA carboxylase activity resulted in decreased malonyl CoA levels and a consequent increase in fatty acid oxidation. GSIS was inhibited over a range of glucose concentrations, as was insulin secretion elicited by other nutrients that require metabolism in β cells, e.g., leucine, glutamine, and ketoisocaproic acid. In contrast, insulin secretion stimulated by KCl was not affected. These results seem to support the LC-CoA model but some caution in interpretation is warranted. A particular concern is that chronic lowering of malonyl CoA levels could result in depletion of stored lipids. Depletion of β -cell lipids in nicotinamide-treated animals or humans^{104,105} or in hyperleptinemic rats¹⁰⁶ blocks insulin secretion in response to glucose and many other secretagogues. Interestingly, in both cases GSIS is immediately restored by provision of FFA. These findings clearly support an essential role for lipids in regulation of insulin secretion, possibly at the level of membrane lipid turnover or acylation of regulatory proteins. The latter possibility is also supported by recent studies in which insulin secretion was inhibited by addition of cerulenin, an inhibitor of protein acylation.⁹⁸ However, while a minimal pool of lipids may be essential for normal regulation of insulin secretion, the aforementioned studies with malonyl CoA decarboxylase adenoviruses and triacsin C provide strong evidence that glucose sensing can occur in the absence of a rise in malonyl

CoA and despite acute perturbation of lipid metabolism.

Further study will be required to fully understand the role of lipids in regulation of insulin secretion. From the foregoing experiments, it is clear, at least in highly glucose-responsive INS-1-derived cell lines, that perturbation of the normal link between glucose and lipid metabolism and complete blockade of glucose-induced increases in malonyl CoA accumulation have no impact on GSIS. However, it remains possible that an important signal is generated not from changes in the rate of fatty acid oxidation, but rather by flow of LC-CoA into esterification pathways, as has also been suggested by Prentki and associates.¹⁰⁷ This issue remains to be clarified, as does the mechanism by which fatty acids potentiate GSIS.

One possible role for lipids in insulin secretion is their further metabolism to generate by-products with signaling properties. For example, it has been suggested that insulin secretion from pancreatic islets may be mediated in part by activation of phospholipase C (PLC) and phosphoinositide hydrolysis.⁴⁷ In freshly isolated rat islets, there is a 15-fold increase in insulin secretion in response to elevated glucose, and this response typically occurs with a biphasic pattern. By contrast, mouse islets lack a sustained second phase of GSIS. It has been proposed that the absence of the second phase response in mouse islets is due to their relatively low capacity for PLC-mediated hydrolysis of phosphoinositides.¹⁰⁸ Indeed, mouse islets have reduced expression of the β and δ isoforms of PLC, while the γ 1 isoform is expressed at a similar level as in rat islets.¹⁰⁸

PLC-mediated hydrolysis of phosphoinositides would result in generation of inositol trisphosphate (IP_3) and diacylglycerol, which could link to insulin secretion via mobilization of intracellular Ca^{2+} stores and activation of protein kinase C, respectively. PLC isozyme expression has been characterized in normal rat islets and two insulinoma cell lines, INS-1 and β G 40/110.¹⁰⁹ β G 40/110 is a glucose-responsive cell line derived from RIN 1046-38 insulinoma cells by stable transfection with plasmids encoding human insulin and glucokinase.^{110,111} Rat islets contain abundant PLC δ 1 expression, but both cell lines completely lack this isoform. In addition, both lines have similar or slightly reduced levels of expression of PLC β 1, β 2, β 3, δ 2, and γ as found in fresh rat islets. In an attempt to determine whether increases in inositol phosphate (IP) levels enhance insulin secretion, PLC δ 1, β 1, or β 3 were overexpressed in INS-1 or β G 40/110 cells using recombinant adenoviruses.¹⁰⁹ In these cell lines, overexpression of PLC isoforms resulted in little or no enhancement in IP accumulation and no improvement in insulin secretion in response to glucose or carbachol, despite the fact that the overexpressed proteins were fully active in cell extracts. Overexpression of the β 1 or β 3 isoforms in normal rat islets elicited a larger increase in IP accumulation, but again with no effect on insulin secretion. Since the effect of carbachol on insulin secretion is thought to be mediated through muscarinic receptors that link to the $G_{q/11}$ class of heterotrimeric G proteins, $G_{11\alpha}$ was also overexpressed in INS-1 cells, either alone or in concert with overexpression of PLC β 1 or β 3.¹¹² Overexpression of $G_{11\alpha}$ enhanced IP accumulation, an effect slightly potentiated by co-overexpression of PLC β 1 or β 3, but again, these maneuvers were without effect on glucose- or carbachol-stimulated insulin secretion. In sum, these studies showed a lack of correlation between IP accumulation and insulin secretion in INS-1 cells, β G 40/110 cells, or cultured rat islets during stimulation with glucose or carbachol. However, it remains possible that the loss of fuel signaling engendered by complete lipid depletion in islets¹⁰⁴⁻¹⁰⁶ could be due to a requirement for some minimal level of PLC-mediated phosphoinositide metabolism.

FIGURE 14-5A. Adenovirus-mediated expression of malonyl CoA decarboxylase (MCD) in INS-1-derived 832/13 cells blocks glucose-induced malonyl CoA formation, but has no effect on glucose-stimulated insulin secretion. **A.** 832/13 cells were treated with recombinant adenoviruses containing different cDNA constructs encoding MCD (see reference 102 for details) or, as a control, a virus expressing the β -galactosidase gene (AdCMV- β GAL). After viral treatment, cells were cultured in 3 mM glucose for 24 hours, and then switched to buffer containing either 3 or 15 mM glucose for 30 minutes prior to extraction and measurement of malonyl CoA. Data represent the mean $\pm$ SEM for three independent measurements. The asterisk (*) indicates that the malonyl CoA level at 15 mM glucose was significantly higher than at 3 mM glucose in the AdCMV- β GAL-treated control cells, with $p < 0.001$.

Insulin Signaling in β Cells

A traditional topic of debate in islet research has been whether insulin controls its own expression and secretion. Recent studies suggest that the insulin receptor and other key components of the insulin signaling cascade are expressed in islet β cells.^{113–117} Furthermore, exposure of β TC3 cells to glucose or exogenous insulin results in tyrosine phosphorylation of the insulin receptor and IRS-1, suggesting that the expressed signaling molecules are fully functional in β cells. However, conflicting results have been obtained in insulin-secreting cells with wortmannin, an inhibitor of a key enzyme of insulin signaling, phosphatidylinositol-3-kinase, possibly relating to the different experimental conditions employed.^{112,121} In contrast, a role for insulin in regulating its own expression and that of other genes important for β -cell function has been more clearly defined.^{122,123}

An important role for signaling molecules implicated in insulin action has also emerged from studies with knockout mice. For example, mice deficient in insulin receptor substrate-2 (IRS-2) become insulin resistant due to impaired insulin signaling in skeletal muscle and liver.¹¹⁵ Interestingly, while normal mice or mice with IRS-1 knocked out exhibit a compensatory increase in insulin secretion; this does not occur in IRS-2-deficient mice. Instead, they

exhibit a progressive loss of β -cell mass and eventually develop diabetes. These results suggest that IRS-2 plays an important role in regulation of β -cell proliferation and compensation in insulin-resistant states, and implies the existence of signals that balance insulin action and insulin secretion via IRS-2-mediated β -cell expansion.

More recently, mice with specific knockout of the insulin receptor in β cells were created by crossing a strain homozygous for an insulin receptor allele containing loxP sites with one expressing cre recombinase; the latter was under control of the insulin promoter, thereby directing the genetic deletion to pancreatic β cells.¹¹⁷ The mice developed impaired glucose tolerance, caused by a perturbation of the first phase of insulin secretion in response to a glucose challenge, while the response to arginine remained intact. In addition, insulin content and islet size were slightly decreased in insulin receptor-deficient mice. These findings have led to reexamination of IRS-1-deficient mice with respect to islet function.¹²⁴ These animals were initially reported to be highly insulin resistant but normoglycemic due to an effective compensation by islet cell hyperplasia.¹²⁵ More recently, it was found that while basal insulin levels are elevated in the IRS-1-deficient mice, glucose- and arginine-stimulated insulin secretion is impaired. Similar findings have been

FIGURE 14-5 (continued). B. 832/13 cells were treated with the indicated adenoviruses and cultured for 24 hours in medium containing 3 mM glucose. Insulin secretion was then measured by incubating cells in HBSS containing either 3 or 15 mM glucose for 2 hours. Results represent the mean $\pm$ SEM for eight independent experiments. ** p < 0.01; *** p < 0.001. (Data used, with permission, from Mulder, et al.¹⁰²)

reported in isolated islets and in immortalized cell lines derived from the IRS-1-deficient mice.¹²⁴ Insulin content in individual islets of these animals is also decreased, whereas total pancreatic insulin content is not altered due to the increase in total islet mass. Interestingly, morphological examinations showed that the secretory granules are smaller and more condensed in the IRS-1-deficient mice. Also, there is the presence of autophagic vesicles, which are lacking in the wild type β cells.

In a complementary approach to the knockout studies, the effect of stable overexpression of IRS-1 has been studied in clonal mouse β cells, the β -TC-F7 line.¹²⁶ This maneuver increased fractional release of insulin, when glucose was raised from 0 to 15 mM, while surprisingly, insulin content was decreased. The glucose-induced increase in intracellular Ca^{2+} was not affected, whereas basal cytoplasmic Ca^{2+} levels were increased. The authors suggest that the mechanism by which basal Ca^{2+} levels are elevated may be inhibition of Ca^{2+} uptake into the endoplasmic reticulum, possibly secondary to an increase in protein kinase C activity. Similar findings were made in single β cells.¹²⁰

At this point, it appears that the insulin receptor is expressed in β cells and that known insulin-stimulated signal transduction pathways are operative. The surprising implication from studies involving genetic manipulation of insulin receptor or insulin signal transduction molecules in β cells is that insulin plays a role in β -cell stimulus-secretion coupling, by augmenting its own secretion. The mechanisms for this are still unclear, particularly in light of the discrepant findings with wortmannin, although Ca^{2+} metabolism may be involved. Another cautionary note about the findings with transgenic animals is that despite the normal appearance of islets in animals with β -cell insulin receptor knockout, the possibility that the altered β -cell function in these animals is due to a developmental impairment has not been rigorously excluded. Further confusion has arisen from the recent finding that transgenic mice carrying a double conditional knockout of the insulin receptor in pancreatic β cells and skeletal muscle unexpectedly exhibited an improvement of their glucose homeostasis compared with the single conditional knockout of the insulin receptor in β cells.¹²⁷ This improvement was due in part to an enhancement of GSIS.

GENETIC ENGINEERING APPLIED TO INSULIN REPLACEMENT THERAPY FOR DIABETES

The recently concluded Diabetes Control and Complications Trial (DCCT) has clearly demonstrated the importance of tight glycemic control for limiting onset and progression of the crippling secondary complications of type 1 diabetes mellitus (T1DM). Unfortunately, improvement in glycemic control via self-injection of insulin requires a high level of compliance and discipline, and places the patient at significantly enhanced risk for dangerous hypoglycemic episodes. Transplantation of human pancreatic islets, usually involving instillation of isolated islets via the portal circulation and immunosuppression, has been investigated as an alternative to insulin injection therapy, but historically has had very limited success.¹²⁸ Recently, however, in a trial in Edmonton, Alberta, Canada, a combination of mild immunosuppressive agents was used in conjunction with freshly isolated islet tissue to achieve insulin independence in seven successive patients studied for up to 1 year posttransplant.¹²⁹

Two major issues that remain to be overcome in order for cell-based insulin therapy of T1DM to become widely applicable include (1) development of a replenishable source of cells capable of delivering insulin in an appropriately regulated and stable fashion, and (2) development of methods for ensuring immunoprotection of transplanted cells. Because of the difficulty and cost associated with islet isolation and pancreas transplantation, there has been an increasing emphasis on application of the tools of molecular biology for development of novel insulin replacement therapies, including engineering of insulin-secreting cell lines, stem cell development, and expression of insulin in nonislet cells via gene therapy. We will close the chapter by reviewing the current status of these efforts.

Engineering of Cell Lines for Glucose-Stimulated Insulin Secretion

Two basic approaches for engineering of surrogate β cells have emerged. The first involves genetic engineering of preexisting lines to enhance their function. Key goals include overexpression of the human proinsulin cDNA and development of cells that regulate their insulin secretion in response to glucose and its potentiators. Early experiments of this type were carried out in the neuroendocrine cell line AtT-20ins, which is derived from ACTH-secreting corticotrophs of the anterior pituitary. These cells normally do not express the insulin gene, but upon transfection with a plasmid containing the human proinsulin cDNA, are shown to secrete the mature insulin polypeptide.^{130,131} Insulin secretion from AtT-20ins cells can be stimulated by agents such as forskolin or 3-isobutyl-1-methylxanthine (IBMX), but not by glucose. Stable expression of GLUT-2 in AtT-20ins cells conferred glucose-stimulated insulin secretion, albeit with a maximal 2.5-fold response occurring at a glucose concentration of approximately 50 μ M.^{77,78} However, transplantation of engineered AtT-20ins cells into nude rats caused insulin resistance, apparently secondary to ACTH secretion from the cells and resultant adrenal hyperplasia.¹³² Thus while these cells served as a proof of principle, they are unlikely to be useful for insulin replacement therapy.

More recent work has instead focused on rodent insulinoma cell lines such as RIN 1046-38 and INS-1. RIN 1046-38 cells respond to glucose, but this response is maximal at subphysiologic glucose concentrations and is lost as a function of time in culture, in concert with loss of expression of GLUT-2 and glucokinase.^{13,133} As detailed earlier, INS-1 cells exhibit a modest (two- to fourfold) response to glucose concentrations in the physiologic

range, but genetic engineering methods have been applied to procure robustly glucose responsive INS-1-derived subclones.⁹⁹

Using a process of "iterative engineering," or the stepwise stable transfection of cells with plasmids containing different genes and discrete antibiotic resistance markers, RIN 1046-38-derived cell lines have been developed with insulin content comparable to that measured in cultured human islet preparations (2.5–4.0 μ g insulin/ 10^6 cells).¹¹⁰ Installation of GLUT-2 and glucokinase genes in these cells by stable transfection conferred a large enhancement in glucose-stimulated insulin secretion.^{110,111} The multiply engineered lines increase insulin secretion by six- to eightfold in response to glucose, and this response was potentiated by agents that raise cAMP. The engineered cell lines exhibit a maximal response to glucose at low concentrations (0.05–0.25 mM), but when incubated with 5-thiogluconase, an inhibitor of low- K_m hexokinase activity, maximal responsiveness occurred at 3–5 mM glucose.¹¹¹ These data suggest that further adjustment of glucose sensing to simulate the response threshold of the β cell (4–5 mM) could be achievable by stable suppression of low- K_m hexokinase activity, possibly via gene knockout by homologous recombination.

One advantage of the stable transfection approach outlined above is that it may provide a remarkable genetic and phenotypic stability in the engineered cell lines. Thus transplantation of unencapsulated engineered RIN cell lines into nude rats revealed that stably-integrated transgenes were expressed at constant levels in the *in vivo* environment for up to 48 days, the longest experiment performed.¹¹⁰ Several endogenous genes expressed in normal β cells, including rat insulin, amylin, sulfonylurea receptor, and glucokinase were also stably expressed in the insulinoma lines during these *in vivo* studies. Endogenous GLUT-2 expression, in contrast, was rapidly extinguished (within 10 days of cell implantation). The loss of GLUT-2 was not observed in engineered cell lines in which GLUT-2 expression was provided by a stably transfected transgene.¹¹⁰

The second approach to generation of new cell lines is to direct expression of a transforming gene, generally SV40 T-antigen, to β cells of transgenic mice via the insulin promoter/enhancer. Cell lines derived by transgenic expression of T-antigen in β cells exhibit variable phenotypes.^{134–137} In some cases, these differences have been correlated with expression of glucose transporters and glucose phosphorylating enzymes. Some lines such as β TC-6 and β TC-7 were shown to have a glucose response that resembles that of the islet in magnitude and concentration dependence.¹³⁵ These cells express GLUT-2 and contained a glucokinase:hexokinase activity ratio similar to that of the normal islet when studied at low passage number, but with time in culture GSIS became maximal at low, subphysiologic glucose concentrations. Accompanying this shift in glucose dose-response was a large (approximately sixfold) increase in hexokinase expression. More recently, soft agar techniques have been used to derive new clonal isolates of β TC-6 cells (such as the clone β TC6-F7), which appear to retain differentiated function for longer periods of time in culture.¹³⁷ However, the long-term stability of these cell lines is still unclear.¹³⁸

Controlling the growth rate of T-antigen-expressing cell lines by a strategy of conditional immortalization may allow better control of fuel homeostasis. The recently derived β TC-tet insulinoma cell lines express T-antigen under control of a tetracycline-regulatable promoter, such that when tetracycline or its analogues are present, the cells decrease their expression of the transforming gene and stop growing.¹³⁹ Syngeneic transplantation of these cells

in an unencapsulated state into mice resulted in rapid cell growth and development of hypoglycemia in the absence of tetracycline, but in animals implanted with slow release tetracycline pellets, tumor mass was controlled and normoglycemia was maintained for a period of 150 days. It remains to be determined whether expression of critical glucose-sensing genes is stably maintained in β TTC-tet cell lines during tetracycline treatment.

Engineering of Cell Lines for Resistance Against Immunological Attack

As new rodent cell lines with attractive physiological properties are being developed, insights into strategies for immunoprotecting such cell lines are also emerging. As is the case with strategies for engineering of physiological responsiveness, work to date on immunoprotection has been limited to animal cell lines, as appropriate human β cell lines are not yet available. However, it is hoped that emerging approaches will be rapidly transferable to human cells as they are developed.

Immunologic destruction of β cells in type 1 diabetes is thought to be a T-cell-dependent process. Infiltration of pancreatic islets by mononuclear cells of the immune system, mostly macrophages and T lymphocytes, precedes β -cell destruction in human subjects with T1DM and in non-obese diabetic (NOD) mice. Impaired function and destruction of β cells appears to result from direct contact with islet-infiltrating cells and/or exposure to inflammatory cytokines that they produce.^{140–143} Since cytotoxic T-cells destroy target cells via docking to MHC class I molecules, resulting in T-cell receptor activation, one approach for protecting unencapsulated islets is MHC class I “masking” by pretreatment with specific antibodies¹⁴⁴ or suppression of MHC class I expression by antisense strategies or by expression of the adenovirus E3 gene.^{145,146} These maneuvers have been demonstrated to slow destruction of islet xenografts¹⁴⁴ or cell lines transplanted as allografts.¹⁴⁵ In addition, expression of the entire E3 gene in transgenic mice engineered for virus-induced, β -cell-specific autoimmunity prevents β -cell destruction, although peri-insulitis is still observed.¹⁴⁶ However, it is as yet unclear whether E3 expression will be sufficient to protect transplanted cell lines from immune destruction in all cases. In fact, the protection afforded by E3 expression in transplanted mouse islets is demonstrable in some mouse strains but not in others.¹⁴⁵ Another approach that has been taken is the expression of “protective” or Th2 cytokines such as IL-4 or IL-10 in β cells. Expression of IL-4 in β cells does in fact provide effective protection against β -cell destruction and insulinitis in transgenic NOD mice.¹⁴⁷ However, expression of IL-4 fails to protect NOD islets when transplanted into diabetic NOD mice, and also fails to protect islets transplanted from one strain of mouse to another (allografting) in the absence of any autoimmunity.¹⁴⁸ Thus it appears that local production of IL-4 may not be sufficient to provide protection for transplantation of cell lines into animals or humans with diabetes. A final approach that has garnered attention is the engineering of cotransplanted cell lines for expression of Fas ligand (FasL). In one recent study, syngeneic myoblasts engineered for FasL expression provided protection for a cotransplanted islet allograft in mouse experiments.¹⁴⁹ While initially highly encouraging, a subsequent study involving expression of FasL in transplanted islets showed accelerated rather than slowed immunologic destruction of the graft.¹⁵⁰ The reasons for these discrepant results are not yet apparent and further investigation of the FasL approach will be required.

An alternative approach to preventing T-cell/graft interaction is to encapsulate cells in a cell-exclusionary membrane or device. Such an approach obviates the need for suppression or masking of MHC class I expression in the cells to be implanted. Furthermore, implantation of cells in an encapsulated form, particularly when all the cells are within a single device (macroencapsulation), can allow immediate localization or retrieval of cells should problems with cell performance or other complications be encountered. When dealing with cells encapsulated in this fashion, immunoprotective strategies become focused on mechanisms for preventing cell damage in response to small, soluble mediators of the immune response. One approach is to identify and express candidate genes that may interfere with this kind of cell damage. These include the anti-apoptotic gene *bcl-2* and related family members;^{7,151} enzymes involved in metabolism of toxic oxygen radicals present at low abundance in β cells such as superoxide dismutase, catalase, or glutathione peroxidase;^{152,153} other molecules that interfere with the known signal transduction pathway of inflammatory cytokines, such as dominant-negative FADD domain proteins, which partially block TNF- α signaling;^{154,155} or dominant negative forms of the IL-1 receptor interacting protein MyD88.¹⁵⁶ Expression of anti-apoptotic members of the *bcl* gene family have been reported to confer partial protection against cytokine mixtures,^{7,151} but at high levels of expression, these proteins may also impair glucose metabolism and glucose-stimulated insulin secretion.¹⁵⁷

An alternative, more general approach is to develop cell lines with resistance to inflammatory cytokines. This has been recently achieved by culture of INS-1 cells in incrementally increasing concentrations of IL-1 β + IFN- γ , resulting in isolation of clones resistant to the cytotoxic effects of the two cytokines (Fig. 14-6).¹⁵⁸

The resistance to IL-1 β as a result of the selection procedure is permanent, while the resistance to IFN- γ is transient and inducible.¹⁵⁸ By following the known pathways of IL-1 β and IFN- γ signaling, cytokine resistance in the selected cells was shown to be associated with altered activity or expression of transcription factors. Thus the permanent resistance to IL-1 β was linked to impaired NF- κ B translocation.¹⁵⁸ Selected cells maintained in cytokines were also found to contain very high levels of the transcription factor STAT-1 α , whose translocation to the nucleus is mediated by interaction with IFN- γ receptor and its associated Janus kinase (JAK).¹⁵⁹ Furthermore, adenovirus-mediated overexpression of STAT-1 α in cytokine-sensitive INS-1 cells confers partial resistance to the cytotoxic effects of IFN- γ or IFN- γ + IL-1 β (Fig. 14-7).¹⁵⁹ It remains to be determined whether other factors also participate in the development of complete cytokine resistance. Comparison of gene expression profiles in cytokine-resistant and cytokine-sensitive INS-1-derived cells may allow a more complete understanding of pathways leading to robust resistance to soluble mediators of the immune response.

Approaches to Human Cell Therapy of Diabetes

Important gains have been made in recent years in identifying and developing cell lines that can perform key functions of the normal islet β cell, and in devising strategies that may aid in protecting such cells when transplanted into an immunocompetent host. It is hoped that lessons learned from both transgenic and cellular engineering approaches will be applicable to development of cell lines suitable for treatment of human diabetes. However, it is uncertain if rodent or other xenogeneic cell lines will serve as a useful vehicle

FIGURE 14-6. A selection procedure for isolation of cytokine-resistant INS-1 cells. INS-1 cells were grown in the presence of iterative increases in concentrations of IL-1 β + IFN- γ over a period of 8 weeks, as described in Chen, et al.¹⁵⁸ At the end of the 8-week selection procedure, one group of selected cells was cultured for 2 additional months in the continual presence of 10 ng/mL IL-1 β + 100 U/mL IFN- γ (INS-1_{Res}), while a second group of cells had cytokines withdrawn for the 2-month period (INS-1_{Res} in normal medium). These two cell populations and unselected INS-1 cells (INS-1) were cultured overnight in the absence of cytokines and then subjected to acute treatment (48 hours) with 10 ng/mL IL-1 β + 100 U/mL IFN- γ or with conditioned medium from LPS-stimulated rat peripheral blood mononuclear cells (LPS-stimulated PBMC). Viability of the three cell populations was estimated with the MTT viability assay, relative to each group of cells cultured in normal medium without cytokines or PBMC-conditioned medium, which were scored as 100% viable (medium control).

for delivery of insulin to human patients. Problems with such cell lines include their potential transmission of adventitious infectious agents (e.g., retroviruses) and their leak of xenoantigens, resulting in a hyperaggressive immune response that may destroy transplanted cells even if they contain protective genes. It is therefore imperative to develop human cell lines that can serve as functional allografts. The genetic engineering approaches just described are likely to be applicable to the development of such lines. The problem is with the lack of stable human β -cell lines, or alternatively, an expandable population of stem cells that can serve as the starting material for molecular manipulation. We close the chapter by evaluating several approaches for dealing with this problem that have emerged recently.

One approach to procuring an expandable supply of human β cells is to isolate stem cells that can be grown in culture and induced to differentiate to a β -cell phenotype. Two types of stem cells may be suitable for this purpose. First, there is evidence to suggest that the pancreatic ducts contain cells with the capacity to expand and differentiate to normal islet tissue. Thus, islet neogenesis from pancreatic ductal structures has been demonstrated in several models of islet regeneration, including the partially pancreatectomized rat,¹⁶⁰ and in mice transgenic for expression of IFN- γ in islet β cells.¹⁶¹ More recently, two reports have shown that the portion of the pancreas that remains after islet harvesting can yield islet-like structures when cultured in defined tissue culture media, and that resultant cell clusters express insulin and secrete the hormone in response to known stimulators of secretion.^{162,163} These studies provide some encouragement for the idea that the pancreas

contains pluripotent stem cells that can be harnessed to procure functional islets. However, major issues remain to be overcome, including the relatively low and quite variable insulin content achieved in the studies performed to date, and the absence of unequivocal evidence that the insulin-containing cells are derived from stem cells rather than from preexisting β cells. Therefore, a key goal for the future is the isolation and characterization of the putative stem cells from the mixed cellular populations found in the ductal cultures.

The second type of stem cell that may have utility for procurement of functional pancreatic islets is the embryonic stem cell. A recent report has used a cell-trapping system to isolate insulin-producing cells from mouse embryonic stem cells.¹⁶⁴ This involved construction of a vector containing a fragment of the human insulin gene driving expression of a neomycin resistance gene, and a separate transgene consisting of a constitutive promoter (phosphoglycerate kinase) driving expression of a hygromycin resistance gene. This construct was used to transfect mouse embryonic stem cells by electroporation, and transfected cells were selected with hygromycin. Selection of insulin-expressing subpopulations of transfected cells was then achieved by culture of cells in neomycin (G418). Initial populations of insulin-expressing cells procured by culture in the presence of nicotinamide and high (25 mM) glucose had very low insulin content and no response to secretagogues. However, further culture of these cells at low glucose (5.6 mM) resulted in a progressive increase in insulin content and modest glucose-stimulated insulin secretion. Implantation of these cells into streptozocin-induced diabetic mice resulted in partial normaliza-

FIGURE 14-7. Adenovirus-mediated expression of STAT-1α in a cytokine-sensitive INS-1-derived cell line confers resistance to cytokine-induced cytotoxicity. **Inset.** INS-1 cells were treated with the indicated concentrations of AdCMV-STAT-1α for 12 hours, and then incubated in fresh medium for 24 hours, prior to cell harvesting and immunoblot analysis with an anti-STAT-1α antibody. Control cells were incubated for the same time period but without virus treatment. The cytokine-sensitive cell line 834/40 was treated with 1×10^9 pfu/mL of AdCMV-STAT1α, the same amount of AdCMV-βGAL virus, or no virus. These cell groups were cultured in normal medium for 24 hours, and then treated with 100 ng/mL IL-1β, 100 U/mL IFN-γ, or both cytokines for 48 hours. Cell viability was then determined with the MTT assay. Data represent the mean $\pm$ SEM for four independent experiments. Symbols refer to comparisons of viability of STAT-1α overexpressing cells to other groups, as follows: @, $p < 0.001$ versus untreated control, $p < 0.03$ versus AdCMV-βGAL-treated control; #, $p = 0.05$ versus untreated control, $p < 0.007$ versus AdCMV-βGAL-treated control; *, $p < 0.002$ versus either control group. (Data used, with permission, from Chen, et al.¹⁵⁹)

tion of blood glucose levels and improved glucose tolerance during oral glucose or meal challenges. This study provides important proof of principle for the concept that embryonic stem cells can be used to procure cells that resemble pancreatic islets in several important aspects. However, it remains to be determined if the same or related technologies will be applicable to human embryonic stem cells, and whether political considerations will allow such work to progress at an optimal pace. Furthermore, it will also be important to determine whether the insulin-producing cells that are derived by these methods can be induced to become fully differentiated, which could involve application of some of the genetic engineering approaches described earlier.

While human cell line and stem cell development continues, others have investigated the possibility that gene therapy can be used to deliver insulin from extrapancreatic tissues. Three recent publications are notable in this regard.^{165–167} In one study, the investigators engineered an insulin molecule containing a short peptide loop connecting the A and B chains of the molecule that allows appropriate folding and interaction of the two chains without a requirement for proteolytic processing.¹⁶⁵ The cDNA encoding this construct was placed under the control of the liver pyruvate kinase promoter and delivered with an AAV vector to liver of streptozocin-induced diabetic mice. Animals that received this vector exhibited near-normalization of blood glucose levels. However, the insulin

secretion response to an oral glucose tolerance test was clearly delayed relative to animals with intact islets, as would be expected given that control of insulin production by glucose in the transgenic mice occurs via activation of the pyruvate kinase promoter, a much slower process than glucose-stimulated insulin exocytosis in normal islets. Transgenic mice were also susceptible to postprandial hypoglycemia, because insulin production persisted beyond the point at which glucose levels began to fall.¹⁶⁵ It must also be noted that further development of viral gene transfer vectors is required to ensure efficacy and patient safety before constructs of this type can be delivered to human diabetic patients. An interesting alternative hepatic engineering strategy that has recently appeared involves adenovirus-mediated expression of a key islet transcription factor, PDX-1.¹⁶⁶ Remarkably, this maneuver results in activation of insulin gene expression in liver of streptozocin-diabetic mice, and partial normalization of their blood glucose levels. While similar concerns can be raised about this approach as for the insulin analogue idea (poor regulation of insulin secretion from liver, concerns about vector efficacy and safety in humans), the PDX-1 study may have broader implications in the context of inducing differentiation of nonislet or stem cells in culture. Finally, a recent study has investigated the expression of human proinsulin under control of the glucose-dependent insulinotropic polypeptide (GIP) promoter in transgenic mice.¹⁶⁷ Initial testing of the construct in gut K

cells revealed correct proteolytic processing of proinsulin to insulin, presumably mediated by expression of the proprotein convertases PC1/3 and PC2 in the gut cell line. Furthermore, modest glucose-stimulated insulin secretion (twofold response as glucose was raised from 1 to 10 mM) was demonstrated in the transfected cells. Expression of proinsulin in transgenic mice under control of the GIP promoter resulted in expression of the transgene in gut, normalization of blood glucose levels in streptozocin-induced diabetic mice, and a more normalized response to an oral glucose bolus than observed with the pyruvate kinase/single-chain insulin AAV approach. Whether these intriguing results can be developed into a new strategy for treatment of human diabetes again awaits the development of safe and efficacious gene therapy vectors for gene transfer to the gastrointestinal tract.

Immunology Relevant To Diabetes

Charles A. Janeway, Jr.

F. Susan Wong

Type 1 or insulin-dependent diabetes mellitus (T1DM) is widely considered to be an autoimmune disease. This hypothesis is based on a number of independent findings, including the presence of a lymphocytic infiltrate known as insulinitis in the islets of recently diabetic individuals, the specificity of pancreatic β -cell destruction, the observation that diabetic patients transplanted with identical twin pancreas grafts rapidly and selectively destroy the β cells in the grafted tissue, the presence of antibodies to islet antigens, and numerous studies in animal models.¹ Thus, to understand the pathogenesis of T1DM, one must have a working knowledge of immunology and of autoimmune diseases.^{2,3} In this chapter, relevant features of the immune system will be briefly described, followed by a discussion of the autoimmune pathogenesis of type 1 diabetes in humans as illustrated by studies of experimental animal models. Following that discussion, the possibility of treating, and more importantly of preventing, type 1 diabetes will be discussed. See Chap. 20 for a discussion of the clinical findings and pathophysiology of type 1 diabetes in humans.

ADAPTIVE IMMUNITY: THE CLONAL SELECTION OF ANTIGEN-SPECIFIC LYMPHOCYTES

The immune system has as its primary function the defense of the host against infection. Two discrete classes of immunity exist. Innate immune defense mechanisms such as phagocytosis defend against a broad range of microorganisms but do not provide protection against specific pathogens; these fail to control most pathogens. Adaptive immunity involves immune responses that are specific to individual pathogens and provide long-lasting protection against reinfection with agents previously encountered either naturally or as a result of deliberate immunization. As far as can be determined, innate immune mechanisms have been evolutionarily selected to discriminate self from certain classes of nonself microorganisms. Thus, innate immune mechanisms have no means for recognizing or attacking host cells, and do not participate detectably in autoimmune phenomena. For this reason, this chapter will focus on those aspects of adaptive immune responses that are pertinent to autoimmune disease.

Adaptive immunity operates by clonal selection of individual lymphocytes that recognize specific macromolecular antigens. Clonal selection is the basic operating principle of the adaptive immune response, and is shown schematically in Fig. 15-1. In brief,

the basis of clonal selection is the development within individual lymphocytes of antigen receptors of essentially infinite diversity. During its ontogeny, each lymphocyte generates a unique set of receptor genes that encode a unique cell-surface antigen receptor. As soon as these genes are formed, the receptor is expressed on the surface of the lymphocyte. If the receptor recognizes a ubiquitous self-antigen that is also present in the site of lymphocyte development, this recognition leads to the induction of programmed cell death within the developing lymphocyte. In this way, a repertoire of receptors of random specificity is purged of those receptors that recognize self-antigens.⁴ The remaining cells mature functionally and leave the site of lymphocyte development. These cells are now equipped with receptors that recognize all possible antigens other than ubiquitous self-antigens. If a lymphocyte encounters its specific antigen, the binding of antigen to the lymphocyte receptor triggers the lymphocyte's activation, its proliferation to increase the numbers of specific cells, and the differentiation of its expanded progeny into effector cells that can remove the antigen from the body. Some of its progeny also differentiate into long-lived memory lymphocytes that maintain a heightened state of immunity against the initial antigen. In this way, long-lasting protection against a previously encountered pathogen is generated through clonal selection.

In order to fully understand how the adaptive immune response operates through clonal selection, it is necessary to understand the nature of lymphocyte receptors and the genes that encode them, certain aspects of lymphocyte development, and the activation of lymphocytes by antigen. Finally, it is important to understand the effector mechanisms by which lymphocytes rid the body of pathogens, as these same effector mechanisms are used to damage self-tissues.

LYMPHOCYTE RECEPTORS AND THE GENERATION OF LYMPHOCYTE DIVERSITY

There are two main categories of lymphocytes, known as *B lymphocytes* and *T lymphocytes*. B lymphocytes develop in the bursae of Fabricius in birds and the bone marrow in mammals, whereas T lymphocytes develop in the thymus (hence their names). These two classes of lymphocytes have distinct receptors that allow them to recognize antigens displayed in different bodily compartments. B lymphocytes are the precursors of antibody-producing cells, and

FIGURE 15-1. Adaptive immunity occurs by clonal selection of lymphocytes. Each lymphocyte develops bearing a single receptor for antigen. Those lymphocytes whose receptors recognize ubiquitous self-antigens will bind antigen as soon as their receptors are expressed on the cell surface, and this induces programmed cell death, purging the initial repertoire of such self-reactive cells. Foreign antigens encountered in the peripheral lymphoid organs induce growth in lymphocytes bearing receptors specific for that antigen; growth is followed by differentiation into effector cells that remove the antigen and generate long-lasting immunologic memory that protects against subsequent encounters with the same antigen.

their cell-surface receptors are identical in specificity to the antibodies they will later secrete into the extracellular fluid and are encoded by the same genes. T lymphocytes, by contrast, have receptors that are specialized to recognize antigens actually produced within the cell; this system allows T lymphocytes to detect and act on cells that are sequestering cytoplasmic pathogens. Although performing quite distinct recognition functions, T- and B-lymphocyte receptors have a great deal in common, having evolved from a common ancestral set of genes and using essentially identical mechanisms to generate the diversity of receptor specificities necessitated by clonal selection.

The diversity of lymphocyte receptors appears to be necessary in order to allow the immune system to recognize all possible pathogens, no matter how recently they arose in evolution. Because microorganisms evolve far more rapidly than their mammalian hosts, the generation of diversity is vested mainly in processes that occur in somatic cells. Thus what evolution has selected for is the ability to generate diverse receptors rather than the genes encoding the receptors themselves.

The antigen recognition sites on antibodies and T-cell receptors are formed by the association of two polypeptide chains, each consisting of a series of similarly folded domains of about 110 amino acids. The amino terminal domain is highly variable in sequence and is called a *variable* or *V domain*. The more C-terminal domains of both B- and T-cell receptor chains have a single amino-acid sequence for all chains of a given type, and are called *constant* or *C domains*. These C domains impart functional capacity to the receptors, whereas the V domains make the extensively varying

antigen-recognition site. Diversity comes from the individual variability of each chain, as well as from the combinatorial diversity produced by pairing two individual variable domains together in all possible combinations to form functional receptors.

There are several distinct sources of diversity that contribute to the variability of variable domains in antibodies and T-cell receptors. Each receptor chain is encoded in clusters of gene segments that together encode the finished receptor. The variable domain is encoded in two or three separate gene segments, which must undergo recombination in developing lymphocytes before they can be expressed as intact proteins. One chain of each receptor, the light immunoglobulin chain and the α chain of the T-cell receptor, is encoded in two separate gene segments, a *V-gene segment* that encodes the first 95 or so amino acids of the domain, and a *J or joining gene segment* that encodes the last 15 or so amino acids. Any V-gene segment can be joined to any J-gene segment, so the total number of distinct V domains that can be generated is the product of the number of V-gene segments times the number of J-gene segments. In the case of immunoglobulin heavy-chain and T-cell receptor β -chain genes, the complete V domain is assembled from a V-gene segment, a J-gene segment, and a gene segment known as *D* or *diversity* that joins the V- to the J-gene segment. The number of distinct immunoglobulin heavy-chain and T-cell receptor β chains that can be formed is the product of the number of V-gene segments, the number of D-gene segments, and the number of J-gene segments. Thus each individual inherits a significant capacity to generate diversity in the form of the different numbers of V-, D-, and J-gene segments for each receptor chain.

A further significant source of receptor diversification occurs at the site of gene segment joining. During the joining process, at least two different processes contribute to diversification at each receptor gene segment junction. First, the precise site at which codons are cleaved and joined is variable. Second, during the formation of gene segment joints, certain nucleotides are removed enzymatically from the site of joining, and more importantly, nucleotides can be added at the site of gene segment joining by two different processes. One of these involves nucleotides of the opposite strand of DNA at the site of gene segment cleavage, forming *palindromic* or *P nucleotides*; the other involves the random addition of *nongenomically encoded* or *N nucleotides* to the ends of the cleaved gene segments by the enzyme terminal deoxynucleotidyl transferase. These two processes together increase the diversity of lymphocyte receptors very significantly, adding at least a factor of 100 to the extent of diversity in gene segment junctions. Because there are two junctions of this type in immunoglobulin heavy chains and T-cell receptor β chains, the amplification in diversity in these double junctions is at least 10,000-fold. More importantly, this tremendous diversity is found in the center of the antigen-recognition site in the folded protein. Thus the region of the receptor molecule most involved in antigen recognition is also the site of the greatest somatic diversification (Fig. 15-2).⁵

Finally, for completeness, it is worth mentioning that B-cell receptors and the antibodies produced from them can undergo further diversification upon stimulation by antigen. This diversification occurs through a process of *hypermutation* in proliferating B cells. This somatic hypermutation is targeted at the rearranged genes encoding the antibody variable domains, and acts in such a way that those B cells whose receptors bind antigen most strongly after somatic hypermutation has occurred are selectively expanded in consequence of their improved antigen binding. Because of this, the efficiency of the antibody response increases enormously during the course of the response. This mode of somatic hypermutation

FIGURE 15-2. The antigen receptors on T lymphocytes consist of two chains, α and β . Each has a variable (V) domain that is assembled from the somatic recombination of gene segments in developing T cells: V and J in the case of α -chains; V, D, and J in the case of β -chains; and a constant domain. The two chains pair to form a disulfide-bonded heterodimeric protein on the surface of T lymphocytes, with antigen recognition resulting from the pairing of the two variable domains. Diversity comes both from joining different combinations of the multiple V, D, and J gene segments, and from differences in the way in which the gene segments are joined together during lymphocyte development. Immunoglobulin genes that encode B-cell receptors and antibodies are assembled in a very similar fashion in developing B cells.

has not been observed for T cells, so all of the diversity in T-cell receptors is generated prior to the expression of the receptor on the cell surface. This has important consequences for differences in tolerance between T and B lymphocytes.

T-LYMPHOCYTE RECOGNITION OF ANTIGENS AS PEPTIDES BOUND TO MOLECULES ENCODED IN THE MAJOR HISTOCOMPATIBILITY COMPLEX

As mentioned earlier, T lymphocytes are specialized to recognize pathogens that reside in the cytoplasmic compartments of the cell. T cells can detect when a cell is harboring a pathogen because the

receptor on T cells recognizes antigen in the form of peptide fragments of the pathogen bound stably to molecules encoded in the *major histocompatibility complex* (MHC). The sole known function of MHC molecules is to present peptide fragments of antigen to T lymphocytes at the surface of infected cells.⁶

MHC molecules have a novel structure in that the complete molecule expressed at the cell surface consists of three polypeptic chains, only two of which are complete polypeptides shared by all MHC molecules. The third chain in MHC molecules consists of a peptide fragment of a cellular or foreign protein. This third peptide element is required for the completion of MHC molecular structure; its presence allows MHC molecules to perform their antigen-presenting function.

MHC molecules exist in two distinct forms, known as *MHC class I* and *class II molecules*. MHC class I molecules have a heavy or α chain encoded within the MHC; this heavy chain associates noncovalently with a non-MHC protein known as β_2 microglobulin. The outer two domains of the heavy or α chain, α_1 and α_2 , are extensively polymorphic and form a cleft into which an eight- or nine-amino-acid peptide binds during the assembly of the MHC class I molecule. MHC class I molecules that lack this third peptide chain are retained in the endoplasmic reticulum; they are highly unstable at 37°C. When MHC class I molecules are synthesized in the endoplasmic reticulum, they rapidly bind to β_2 microglobulin but are retained in the endoplasmic reticulum by their association with a specific peptide transporter known as TAP-1/TAP-2. This heterodimeric ATP-binding cassette protein delivers peptides of 8–15 amino acids generated in the cytosolic compartment of the cell to the lumen of the endoplasmic reticulum. If these peptides bind to the associated empty MHC class I molecules, then the MHC class I molecule completes its folding upon binding peptide and is released from the TAP-1/TAP-2 complex. These stable MHC class I molecules are rapidly transported to the cell surface, where they present the peptide to passing T lymphocytes.

The T lymphocytes that recognize MHC class I-associated peptides are a distinct subclass known as *CD8 T cells*, because they express on their surface a molecule known as CD8. CD8 T cells are specialized to kill cells infected with viruses and other pathogens that replicate in the cytosol. CD8 binds to the lateral face of the MHC class I molecule, whereas the T-cell receptor binds over the peptide-binding cleft at the distal end of the MHC class I molecule. Thus, the T-cell receptor discriminates one MHC class I molecule from another on the basis of the peptide bound to it, whereas CD8 can recognize any MHC class I molecule. CD8 not only binds to MHC class I molecules, but when it binds in conjunction with the T-cell receptor, it greatly facilitates antigen recognition by the T-cell receptor. For this reason, CD8 is known as a *coreceptor molecule*.^{7,8}

The other type of MHC molecule, the MHC class II, presents peptides at the cell surface that derive from proteins degraded in cellular vesicles. MHC class II molecules consist of two polypeptide chains, both of which are encoded within the MHC. The folded structure of the MHC class II molecule is very similar to that of the MHC class I molecule,⁹ but they present peptides derived from different cellular compartments. MHC class II molecules, like class I molecules, are synthesized and assembled in the endoplasmic reticulum. However, MHC class II molecules assemble together with a third, nonpolymorphic chain known as the *invariant chain* or *Ii*, and MHC class II molecules bound to *Ii* are not able to bind peptide. Moreover, the invariant chain appears to direct MHC class II molecules to a particular cellular vesicle in which the invariant chain is degraded by acidic proteases, and peptides present in this

vesicle bind to the now-exposed MHC class II peptide-binding cleft. The invariant chain serves to protect MHC class II molecules from binding peptides in the lumen of the endoplasmic reticulum, and thus avoids the presentation of peptides derived from cytosolic proteins.⁶

MHC class II molecules are recognized at the cell surface by T cells expressing a distinct coreceptor known as *CD4*. Peripheral T cells express either *CD4* or *CD8* and are specific for MHC class II- or class I-associated peptides, respectively. *CD4* T cells have a number of immunologic functions, the most important of which are the activation of infected macrophages to destroy bacteria residing in cellular vesicles and the activation of B lymphocytes to produce antibody. B lymphocytes use their immunoglobulin receptors to convert external antigens into internal ones by binding them and internalizing them into cellular vesicles, and then degrade these proteins into peptides that bind to MHC class II molecules that are expressed on the B-cell surface. Antigen-specific helper T cells recognize those B cells whose surface immunoglobulins effectively bind antigen through the expression of these peptide:MHC class II molecules on the B-cell surface, and selectively activate antigen-binding B cells in this way. In both types of recognition, *CD4* binds to the lateral face of the MHC class II molecule and provides coreceptor function to the T-cell receptor in the recognition of peptides bound to MHC class II molecules (Fig. 15-3).¹⁰

MHC GENE POLYMORPHISM AND ANTIGEN RECOGNITION BY T CELLS

The genes encoding the proteins of the MHC are the most polymorphic genes yet described in the human genome. There are three major loci encoding MHC class I α chains, and four or more encoding MHC class II β chains. At many of these loci,

well over 50 alleles are known to exist. Some of this polymorphism is detectable using antibodies, but the remainder must be detected using either T-cell recognition or nucleic acid sequencing. Human MHC proteins are known as *human leukocyte antigens* or *HLA*s, and human MHC class I molecules are known as HLA-A, -B, and -C. Human MHC class II molecules are known as HLA-D proteins, and are subdivided further into DR, DQ, and DP molecules.

The extensive polymorphism of MHC proteins is largely focused on the peptide-binding groove of the MHC molecule. These polymorphic differences alter the peptide-binding characteristics of the MHC molecule, such that different MHC molecules will present different peptides derived from the same protein. Moreover, the polymorphism of MHC molecules also influences the binding of T-cell receptors to MHC:peptide complexes. Precisely how this occurs is not known, but the same exact peptide bound to two different MHC molecules is readily distinguished by T cells. This phenomenon, which is an intrinsic property of T-cell receptors, is known as *MHC restriction*, because genes at the MHC restrict the antigen-recognition capabilities of individual T-cell receptors (Fig. 15-4).¹¹ In general, MHC restriction is highly MHC specific, such that a given T-cell receptor will recognize its cognate peptide bound only to one or a very few allelic variants of a given MHC molecule. Thus MHC polymorphism affects T-cell recognition in two quite distinct ways: first by altering peptide binding, and second by altering the interaction of the peptide:MHC complex with T-cell receptors. MHC polymorphism is a major genetic factor in determining susceptibility to T1DM and most other autoimmune diseases, and this is likely to reflect the ability of certain MHC allelic variants to present a specific autoantigen to a specific set of T-cell receptors. It also imposes severe constraints on T-cell development, as we will see in the next section.

FIGURE 15-3. T cells come in two distinct types, differentiated by expression of the coreceptor proteins *CD4* and *CD8*. *CD8* T cells are specialized to kill cells that present peptide fragments of antigens degraded in cytosol and displayed at the cell surface by MHC class I molecules. The *CD8* coreceptor binds the same MHC class I molecule as the T-cell receptor and contributes to signaling for T-cell activation. *CD4* T cells are specialized to activate cells, such as macrophages and B cells, that present peptide fragments of antigens degraded in cytoplasmic vesicles, such as endosomes and lysosomes, and displayed at the cell surface by MHC class II molecules. The *CD4* coreceptor binds the same MHC class II molecule as the T-cell receptor and contributes to signaling for T-cell activation.

THE DEVELOPMENT AND SELECTION OF LYMPHOCYTES

We have seen in earlier sections that lymphocyte receptors are assembled from gene segments during the development of individual lymphocytes, and that each lymphocyte assembles different gene segments and makes different junctions that encode its unique receptor, so that the totality of receptors forms a highly diverse repertoire of recognition capabilities. Moreover, we have seen that when ubiquitous self-antigens are now encountered by these receptors, the immature lymphocyte is programmed to die, following an apoptotic pathway. In the case of B lymphocytes, these are the only events about which we have information. However, in the case of T lymphocytes, a further event is necessitated by the nature of antigen recognition by T-cell receptors and by the polymorphism of MHC molecules.

We saw in the preceding section that T-cell receptors will only recognize peptides bound to a particular allelic variant of a MHC molecule, and that a given locus may encode as many as 100 different variants. Because the rearrangement of receptor gene segments is completely random, and because an individual can only express 2 out of the possible 100 alleles at a given MHC locus, it is highly likely that most T-cell receptors that form in an individual will not be able to recognize foreign peptides bound to any of that individual's MHC molecules. If such cells were allowed to differentiate, they would fill the periphery with T lymphocytes that are useless. However, this does not occur because T cells must un-

FIGURE 15-4. Antigen recognition by T cells is governed by polymorphism of MHC molecules. The MHC molecules have a deep cleft in their outer aspect that must be occupied by a peptide in order for the molecule to be displayed at the cell surface. The peptide-binding groove is formed by two α helices overlying a β pleated sheet, and the polymorphic residues in the MHC molecule mainly line the peptide-binding groove. Thus, a T cell is specific for a particular combination of peptide and self-MHC, here MHC IIa (left). When this T cell is confronted with a different MHC molecule, here MHC IIb, the nonself-MHC molecules will bind different peptides of a protein (center), or will present a different overall conformation of peptide and MHC molecule when binding the peptide (right). For this reason, T cells show specificity not only for a particular antigen, but also for a particular allelic form of MHC molecule, a property known as MHC restriction in antigen recognition.

dergo a further selective event during their development within the thymus that circumvents this problem. This process is known as *positive selection* because it selects for further maturation only those T cells whose receptors are capable of recognizing foreign peptides bound to a self-MHC molecule. T cells can only mature if their receptors interact appropriately with MHC molecules binding self-peptide likely that they encounter within the thymus. If the T-cell receptor binds self-MHC/self-peptide sufficiently well to trigger T-cell activation, the result is that the T cell dies, a process called *negative selection*, crucial for preventing the development of autoreactive T cells. The weaker signal that triggers positive selection is not yet understood, but it is clearly essential for T-cell development. The consequence of this process is that all T cells that leave the thymus have receptors able to recognize foreign peptides presented by self-MHC molecules.¹² That is, all of the T cells put into the peripheral repertoire appear to be potentially useful. This positive selection event for self-MHC recognition appears to also involve recognition of self-peptides, but at a level too low to trigger T-cell activation, thus avoiding problems of autorecognition.^{13,14}

T-LYMPHOCYTE ACTIVATION, ANTIGEN RECOGNITION, AND COSTIMULATORY SIGNALS

The naïve or unstimulated T cell is a small cell with scanty cytoplasm and condensed nuclear chromatin; it is metabolically very poorly active and cannot carry out any effector function. Moreover, T lymphocytes specific for a given peptide are extremely rare. Thus before a T cell can participate in adaptive immunity, it must recognize antigen and undergo extensive proliferation to increase the number of cells of the relevant specificity, and these must then differentiate into cells capable of mediating effector functions. This occurs over a period of 4–5 days after introducing antigen, and results in an approximately 1000-fold increase in the number of specific cells and their differentiation from resting into active effector cells.

The cells that stimulate T-cell proliferation and differentiation are known as *antigen-presenting cells (APCs)*. For a cell to be able to present antigen to a T cell, it must display the appropriate complex of peptide and MHC on its surface. However, the mere expression of peptide and MHC on the surface of a cell is not sufficient to trigger T-cell proliferation and differentiation into effector

cells. Rather, the T cell needs to receive a signal known as a *costimulatory signal* from the same antigen-presenting cell.^{15–17} The major molecules involved in the costimulation of T-cell growth and differentiation are known as B7.1 and B7.2, related molecules that bind to the T-cell molecule CD28 and a related structure known as CTLA4. The simultaneous binding of the T-cell receptor and its coreceptor to specific peptide:MHC and of CD28 to B7.1 or B7.2 triggers the proliferation of T cells and ultimately their differentiation into effector cells. These effector cells can now act on any cell displaying its specific peptide:MHC ligand, allowing effector cells to act on any cell in the body once activated (Fig. 15-5).

The requirement for costimulation means that only those cells that can express costimulatory molecules can activate naïve T cells. Only a few cell types in the body appear to have this capacity normally, and these are cells that are concentrated in lymphoid organs the site in which naïve T cells are initially activated by antigen. Tissue cells do not express costimulatory molecules. When a naïve T cell recognizes a peptide:MHC complex on a tissue cell, it tends to be inactivated by that encounter. This is important, because not all tissue antigens are expressed in sites of lymphocyte development and most specifically in the thymus, the site of T-cell development. These T cells specific for peripheral self-antigens are not eliminated, but they also are not activated when they encounter their specific antigen on a tissue cell, and this is important in avoiding

FIGURE 15-5. T-cell activation requires the expression of antigen and a costimulatory molecule such as B7.1 or B7.2 on the same antigen-presenting cell (APC). The simultaneous signaling of the peptide:MHC complex to the T-cell receptor (TCR) and of B7.1 or B7.2 to CD28 induces clonal expansion of T cells and their differentiation into effector T cells. Effector T cells can be triggered to mediate their function, such as cell killing, in the absence of costimulatory signals on the target cell. Lymphocytes that encounter antigen in the absence of costimulatory signals may be rendered inactive or tolerant by signals received only through the T-cell antigen receptor.

the induction of autoimmunity. Thus T cells may be rendered tolerant either by deletion through recognition of ubiquitous self-antigens in the thymus or through inactivation by recognition of tissue-specific autoantigens in peripheral tissues. The requirement for costimulation also provides a second level of regulation of immune responses, not only through the presence or absence of antigen, but also through the expression or lack of the costimulator on a given cell.

EFFECTOR FUNCTIONS OF ACTIVATED T CELLS

We have already mentioned that CD8 T cells differentiate into cytotoxic effector cells, able to kill any cell expressing specific peptide:MHC class I complexes on the cell surface. The main function of cytotoxic T cells appears to be to eliminate cells that are infected with viruses. Viruses replicate in the cytosolic compartment of host cells, and peptides deriving from the viruses are presented by MHC class I molecules to CD8 T cells. The killing of these infected cells eliminates the site of viral replication, thus contributing to the clearance of viral infections. The cell must be killed, because cells have no internal means for destroying viral genomes they harbor. CD8 T cells also produce interferon- γ , which can inhibit viral replication, and this is also an important mechanism in controlling viral infection.

CD4 T cells, by contrast, are specialized to activate cells expressing peptide associated with MHC class II complexes. MHC class II molecules are expressed mainly by specialized effector cells of the immune system, including macrophages that are infected with vesicular bacteria or have ingested them, and B lymphocytes that bind antigen and can be activated to produce antibody. The CD4 T cells that activate macrophages make small proteins known as *cytokines* that mediate their effector function, and these are distinct from the cytokines made by the CD4 T cells that activate B cells. These two cell types, known respectively as Th1 and Th2, mediate cell-mediated and humoral immunity, respectively.^{18,19}

EVIDENCE FOR AUTOIMMUNE DESTRUCTION OF PANCREATIC β CELLS IN TYPE 1 DIABETES

As described at the start of the chapter, there is extensive evidence suggesting immunologically mediated destruction of pancreatic β cells in type 1 diabetes. Inflammatory cell infiltrates have been demonstrated in the islets of patients who have died at the time of clinical diagnosis of diabetes.^{20,21} This lymphocytic infiltrate is of mixed lineage, containing macrophages and both CD4 and CD8 T cells.²² Thus it is assumed that the inflammatory infiltrate is related to the destruction of β cells and is in fact driven by the recognition of β -cell autoantigens, because in the absence of β cells found in long-term diabetic patients, no infiltrate is observed.

This idea was given significant impetus by the results of identical twin hemipancreas grafting.²³ Hemipancreatic grafts from an identical twin who did not have diabetes into a sibling who had been diagnosed with T1DM many years previously led to almost immediate normalization of blood glucose. However, in the absence of immunosuppressive drugs, β -cell function was lost rapidly after grafting as β cells were destroyed. The loss of cells was accompanied by an islet infiltrate dominated by CD8 T cells, and selective β -cell destruction was observed in the grafted tissue.²⁴ This destructive process could be inhibited by standard immuno-

suppressive drugs such as cyclosporin A. The process was β -cell specific in that other cells in the islet, the exocrine pancreas, and frequently a syngeneic renal graft were all maintained without any sign of inflammation.

Another sign of the involvement of autoimmunity in the pathogenesis of T1DM is the finding of numerous autoantibodies to different proteins found in β cells. The earliest antibodies to be detected were to islet cells,^{25,26} although the molecules that these antibodies recognized were not known. Subsequently, detection of specific autoantibodies in prediabetic and newly diagnosed patients with diabetes has given us clues to the nature of the autoantigenic targets. These included proteins such as insulin,²⁷ glutamic acid decarboxylase (GAD),^{28,29} and more recently, the tyrosine phosphatase IA-2/ICA512.^{30,31} Others have also been identified, such as bovine serum albumin, insulin receptor, sialoglycolipid, glucose transporter, hsp 65, carboxypeptidase H, 52-kd protein, and 150-kd protein, as reviewed in reference 32.

Because a major role for CD4 cells is to "help" B cells produce antibodies, the production of autoantibodies against proteins found in β cells strongly suggests that helper CD4 T cells specific for peptides contained within these proteins are also activated as part of the diabetic process. Because patients frequently make several different antibodies to distinct proteins, it is likely that the helper CD4 T-cell response in diabetes is quite diverse. However, because the only cells available for study in diabetes in humans are peripheral blood lymphocytes and the quantity of cells likely to be involved in pathogenesis is small, it is difficult to investigate the specificity of potentially pathogenic cells. Nevertheless, it has been possible to clone CD4 T cells to putative autoantigens in humans such as insulin³³ and IA-2,³⁴ but the pathogenicity of these cells has not been established. Although much less studied, there is increasing evidence that CD8 T cells may also be equally important, and the presence of cytotoxic CD8 T cells reactive to GAD has also been shown in recently diabetic patients.³⁵

The final evidence that diabetes is an autoimmune disease is the linkage of susceptibility to genes in the MHC.³⁶ The data linking type 1 diabetes to MHC are strong, but in humans there is no conclusive direct evidence that the susceptibility gene is, in fact, an MHC glycoprotein. Much work has concentrated on the HLA-DQ molecules as being crucial for susceptibility to T1DM, but these data are not conclusive. It is interesting, in this context, that certain DQ alleles are highly protective against type 1 diabetes.³⁷ This further suggests that the pathogenesis of T1DM involves CD4 T cells. However it is clear, in consideration of susceptibility to disease, that larger haplotypes that include the MHC class I molecules are important,^{38,39} and although there is no direct evidence, this has implications for the role of CD8 T cells. Nevertheless, the precise roles of MHC molecules and of T cells in β -cell destruction in humans remain to be elucidated. It may ultimately be possible to begin to study the direct role of these molecules in the future with the development of "humanized" animal models, such as those expressing human MHC molecules.^{40,41}

EVIDENCE FROM ANIMAL MODELS THAT TYPE 1 DIABETES IS AN AUTOIMMUNE DISEASE

A number of animal models exist for type 1 diabetes. The two that are most extensively studied are the spontaneous type 1 diabetes that occurs in BB/W rats⁴² and nonobese diabetic (NOD) mice.⁴³ Type 1 diabetes in these two animal models is sponta-

neous. The disease occurs in the majority of individuals, is strongly controlled by genes mapping to the MHC, is transferable with T cells, and is prevented by T cell depletion. T-cell responses in NOD mice of various ages have been shown to a number of putative autoantigens.^{44,45} The incidence of disease in NOD mice is also altered by a variety of genetic and immunologic manipulations.⁴⁶ The BB rat is rather less susceptible to these manipulations. Autoantibodies are produced in NOD mice to GAD⁴⁷ and insulin,⁴⁸ although this is not universally found in all NOD mouse colonies. Although much of what we believe about autoimmunity in type 1 diabetes comes from studying animal models, it is clear that no single animal model is a faithful mimic of the human disease, and so all studies with these models must be viewed as possible explanations for the human disease that need to be confirmed by direct study of the disease in humans. More recently, mouse models have been developed in which an antigen is expressed as a transgene in the pancreas and T cells recognizing this antigen are also expressed transgenically in the mouse and these mice have provided important insights.^{49,50} As mentioned above, the development of "humanized" animal models expressing human MHC molecules^{40,41} may well be important in the future.

Although much of the early information about the autoimmune pathogenesis of T1DM came from studies of the BB/W rat and these data have been available for a longer period of time, more extensive studies have now been carried out using the NOD mouse. Moreover, one of the major contributory factors to type 1 diabetes in the BB/W rat is a gene that creates a lymphopenic state. Although this gene is not essential for diabetes in the BB/W rat, it does contribute to susceptibility. As lymphopenia is not associated with human type 1 diabetes, this particular characteristic may make studies in the BB/W rat less relevant than those in the NOD mouse. Thus this discussion will focus mainly on the NOD mouse.

The NOD mouse was originally produced as part of a genetic experiment that involved crossing several mouse strains to produce an animal with a high degree of susceptibility to cataracts.⁵¹ In the process of this breeding, mice with a high incidence of type 1 diabetes were produced. This line has now been bred to homozygosity and named the nonobese diabetic (NOD) mouse strain. The incidence of diabetes varies from one colony to another, but under excellent conditions of housing, type 1 diabetes begins to appear around 3–4 months of age, and by 6 months over 90% of the females and up to 60% of the males will have developed type 1 diabetes.⁵²

The genetics of type 1 diabetes in the NOD mouse are complex, involving many genes.⁵³ The single genetic factor that appears to be most important is the MHC, although there are at least 17 other regions that have been identified in the genome which may contribute to susceptibility. The MHC genotype of the NOD mouse is denoted H-2^{g7}, and mice that are homozygous H-2^{g7} have a high incidence of type 1 diabetes, although this is clearly not the only susceptibility factor. NOD mice expressing even a single haplotype of a different MHC genotype are almost completely protected from developing T1DM. There appear to be a number of components of the unique H-2^{g7} haplotype that contribute to susceptibility to T1DM. First, as in many other mouse strains the I-E α chain, the mouse equivalent to the human HLA-DR α chain, is mutant, and thus the I-E MHC class II molecule equivalent to HLA-DR is not expressed in NOD mice. NOD mice transgenic for a normal E α -chain gene are fully protected from type 1 diabetes.⁵⁴ This is reminiscent of the protective effect of some HLA haplotypes for

human T1DM, and clearly identifies a single protective gene. Secondly, the I-A^{g7} molecule, the mouse equivalent of HLA-A also unique,⁵⁵ and it has been shown that changing a single acid at either position 56 or 57 of the I-A^{g7} β chain can render mice diabetes-resistant when the gene is inserted as a transgene. Interestingly, position β 57, which is aspartic acid in all mouse I-A β chains, is serine in the NOD mouse. This is similar to the finding that DQ β chains with aspartic acid at position 5' to be negatively associated with susceptibility to T1DM in casian patients.⁵⁷ Biochemically, there is considerable similarity between I-A^{g7} and DQA1*0301/DQB1*0302, the HLA-DQ molecule most strongly associated with diabetes in humans.⁵⁸ The fact that alleles at MHC class II loci influence susceptibility to type 1 diabetes also suggests that CD4 T cells play an important role either in the pathogenesis of type 1 diabetes or in protection against type 1 diabetes. This might be associated with qualitative differences in T-cell responses to putative β -cell autoantigens; may affect insulin-dependent diabetes mellitus by altering the balance of cytokines produced by β -cell autoreactive T cells.⁵⁹ The direct evidence for the role of MHC class II molecules is beginning to emerge from the mouse model that has the human MHC class II molecule most closely associated with diabetes, namely DQA1*0301/DQB1*0302, previously called DQ8, expressed as a transgene instead of mouse MHC class II molecules,⁴¹ in addition to a transgene directing the expression of the costimulatory molecule B7.1 in the pancreas. These mice develop spontaneous type 1 diabetes. Although the precise role of the MHC in this process, as in human T1DM, is not yet established, the data from transgenic experiments established that it is the MHC loci themselves that are critical for disease susceptibility.

There is also increasing evidence that MHC class I molecules are important in the NOD mouse. The CTS strain of mice that is related to NOD mice has an identical MHC class II region to NOD mice, but differs at one of the MHC class I loci, D^b in the NOD mouse and D^{dk} in the CTS strain,⁶⁰ and these mice have a much lower incidence of diabetes.

Prior to the onset of type 1 diabetes in NOD mice, histopathologic analysis of pancreatic islets of Langerhans reveals an extensive peri-insulitic infiltrate of mononuclear cells, and in some islets invasion of the islet parenchyma and its apparent destruction by lymphocytic cells. β -cell destruction is only observed in islets that are invaded by mononuclear cells; islets that are surrounded by lymphocytes but are not invaded do not show destruction. This argues against a diffusible agent being responsible for β -cell destruction and favors a direct contact mechanism. The infiltrating cells consist of macrophages, dendritic cells, B lymphocytes, CD4 T cells, and CD8 T cells.

There is strong evidence for involvement of T cells in the destruction of pancreatic β cells in type 1 diabetes, and it is likely that both CD4 and CD8 T cells play critical roles. NOD mice carrying a mutation that produces severe combined immunodeficiency (SCID) and that lack lymphocytes, or mice with a mutation such that they do not produce T cells, never develop T1DM, implicating T lymphocytes in the process. Such mice do develop diabetes when they are adoptively reconstituted with lymphocytes. Adoptive transfer can be carried out with bone marrow-derived stem cells, in which case diabetes takes months to develop, or with splenic cells from recently diabetic syngeneic mice, in which case diabetes develops within 3–4 weeks. The acute adoptive transfer of type 1 diabetes with splenic T cells generally requires both CD4 and CD8 T cells.^{61,62} The involvement of MHC class II genes strongly implicates CD4 T cells in the process. In addition, using anti-CD4 ant-

bodies, in the absence of CD4 T cells, insulinitis also does not appear to any great extent and diabetes does not develop.⁶³ However, mice that lack MHC class I molecules due to a mutation in the β_2 microglobulin gene, and that have very few CD8 T cells, do not develop insulinitis or diabetes.⁶⁴⁻⁶⁶ In addition, studies in which anti-CD8 antibodies were injected into young prediabetic NOD mice (before the age of 5 weeks) found that they completely prevented insulinitis and diabetes.⁶⁷ Thus CD8 T cells also play an early role in the pathogenesis of type 1 diabetes. However, the manner in which cells interact and the CD4 and CD8 T-cell responses required to mediate this complex process in the natural history of disease need still to be determined.

In the effort to characterize the immune response that damages the islets in animal models, isolated cloned T-cell lines from the infiltrate of the islets and from spleen have been useful tools. Cloned CD4 or CD8 T cells, like diabetic spleen cells, have been able to transfer disease.^{68,69} In the case of CD4 T cells, it is likely that cells recruited from the recipient provide the required CD8 T cells,⁶⁸ although there are clear examples of single populations of both CD8 T cells⁶⁹ and CD4 T cells that are able to transfer disease when given alone.⁷⁰ Initially, T-cell clones from diabetic spleens that respond to unknown islet antigens, both CD4⁶⁸ and CD8,⁷¹ were isolated. More recently, pathogenic CD4 T-cell clones have been isolated that respond to putative autoantigens—insulin⁷² and GAD.⁷³ Highly damaging CD8 T cells isolated from the islets of young NOD mice also recognize insulin,⁷⁴ although there are other pathogenic cells present in the islets of young mice that have other specificities,⁷⁵ and these differ from those of CD8 T cells isolated from diabetic mice.⁷¹ The cloned T cells from the early infiltrates of NOD mice provide direct evidence that insulin is an important target for both CD4 and CD8 T cells and is the only islet β -cell-specific antigen identified to date. There is also clear evidence for GAD as an autoantigen in this mouse model, although some of it is controversial. There has been much debate about whether a single autoantigen is involved in the initiation of disease, but at present there is no clear evidence, and it is possible that more than one antigen may be a target from the earliest phases of disease.

AUTOIMMUNE PROCESS INITIATION

The normal interaction between the immune system and self-tissues is described as tolerance, the absence of response against self. We have already discussed how tolerance to ubiquitous self-antigens is mediated by deletion of immature T lymphocytes, while tolerance to tissue-specific autoantigens may be mediated by antigen-specific inactivation of T cells that encounter these antigens in the periphery. If autoimmunity represents a failure of self-tolerance mechanisms, which of these mechanisms fails in type 1 diabetes?

There is some suggestion, from the human studies and also from the NOD mouse, that autoreactive cells may be selected rather than deleted in the thymus because there are antigen-presenting cells in the thymus that are able to present peptides of self-antigen such as insulin.^{76,77} It has been postulated that one reason for selection of autoreactive T cells by particular MHC class II molecules, such as I-A^b in the mouse, is that these molecules with their peptide ligands are unstable and therefore stimulation of T cells may not be sufficient to induce negative selection.⁷⁸ Similarly, this may apply to the MHC class II molecule most closely associated with diabetes: HLA-DQA1*0301/DQB1*0302.⁷⁹ In the case of CD8 T cells selected by self-peptides in the context of MHC

class I, autoreactive cells may recognize peptides that bind to the MHC with low affinity, and the concentration of peptide present in the thymus may be insufficient to stimulate deletion. This is one possible mechanism for the selection of autoreactive CD8 T cells that recognize an insulin peptide that binds very poorly to the MHC class I molecule K^d.⁷⁴

Peripheral mechanisms of tolerance that protect against autoreactive T cells are clearly important. It is possible that autoantigens are normally ignored by the immune system. That is to say, the autoantigen is expressed on tissue cells in a form that is recognizable by lymphocytes, and lymphocytes specific for that autoantigen are present but are neither activated nor rendered tolerant. Stimuli that activate T cells specific for these autoantigens can trigger autoimmune processes that then target the tissue itself. A particularly clear example of this is the use of mice transgenic for a viral protein driven by the rat insulin-1 promoter. This leads to expression of the viral protein in pancreatic β cells but does not cause disease. T cells from the transgenic animals are not tolerant to the viral protein. When mice are infected with this virus, the potent antiviral response also causes destruction of pancreatic β cells that express the transgene product.^{49,50} Thus the mouse is ignorant of the presence of the transgene-encoded viral antigen and is operationally tolerant until infected by the virus. This suggests that autoantigens may be relatively unique among self-proteins in being expressed too poorly to induce any kind of tolerance, yet expressed well enough to be the target of immune attack.

Most thinking about the induction of autoimmunity has implicated infection as playing a central role. Infection could provoke autoimmune responses in a number of different ways. In the example just cited, the autoantigen is exactly reproduced by a viral antigen. It has been hypothesized that viruses or bacteria could carry peptides sufficiently similar to self-peptides to trigger autoimmune responses. This mechanism is referred to as molecular mimicry.⁸⁰ Alternatively, inflammatory responses generated against pathogens could release normally sequestered autoantigens from inside cells or behind tissue barriers, and thus lead to a direct autoimmune attack. It has also been suggested that damage may be caused by a bystander mechanism.⁸¹ A study using transgenic mice had suggested that diabetes induced by Coxsackie virus infection could be a direct result of local infection, leading to inflammation, tissue damage, and the release of sequestered islet antigen resulting in the restimulation of resting autoreactive T cells. Finally, pathogens are known to be able to induce potent costimulatory activity on antigen-presenting cells that are otherwise costimulator negative. Thus the pathogen could trigger expression of costimulatory molecules on tissue cells that do not normally express them. In this regard, the expression of the B7.1 costimulator as a transgene product on pancreatic β cells, together with a permissive genetic background, greatly accelerates autoimmune disease in NOD mice.⁸² However, no direct evidence for ectopic expression of costimulator molecules in diabetes has been shown.⁸³

Most recently, it has been suggested that normal apoptotic processes involved in the early remodeling of the pancreas may play a role in triggering the development of diabetes.⁸⁴ There is a wave of apoptosis occurring 2 weeks after birth, and this is increased in rodent models that are prone to diabetes. Under normal circumstances, it is not thought that apoptosis would trigger immune responses. However, it has recently been shown that the highly specialized antigen-presenting dendritic cells are able to take up antigens released by apoptosis and prime cytotoxic T cells. Perhaps the permissive environment that is encoded by genes other

than those in the MHC that are also important in susceptibility may play a role. This mechanism, however, is still speculative.

In conclusion, the autoimmune process in general appears to be triggered by some insult, such as an infection, that upsets a form of tolerance known as immunologic ignorance. The autoimmune response is probably initiated by such an insult.

SUSTAINING AUTOIMMUNE RESPONSES

Most human autoimmune diseases, such as multiple sclerosis, rheumatoid arthritis, and type 1 diabetes, are chronic progressive conditions. Longitudinal studies of individuals at risk of developing type 1 diabetes have suggested that the autoimmune attack takes several years to destroy sufficient β -cell mass to produce overt diabetes.¹ Likewise, in NOD mice, the autoimmune process leading to type 1 diabetes takes at least 3 months to reach completion. These observations suggest that the autoimmune attack must be sustained over long periods of time. Thus, even if a viral infection triggered an initial attack on pancreatic β cells, responses to the autoantigen itself are likely to be required for the production of clinical illness. The tempo of these initial diseases stands in sharp contrast to the tempo of β -cell destruction in human recipients of identical twin hemipancreatic grafts, in which all β cells in the graft can be destroyed within 6 weeks, or to adoptive transfer of T cells from recently diabetic NOD mice into nondiabetic, immunodeficient recipients, in which case all mice become diabetic within 3–4 weeks. Moreover, this adoptive transfer requires only a few percent of the T cells in the diabetic donor for complete penetrance.

These findings suggest that the autoimmune process is normally restrained by mechanisms that protect the target tissue or prevent the development of the autoimmune response. More direct evidence for such restraining cells has been obtained in adoptive transfer experiments using either cell populations or cloned T-cell lines that inhibit the development of type 1 diabetes in NOD mice.^{85–88} Similar results have been reported in several other autoimmune diseases. Some of these cells have been cloned directly from islets^{85,86} or from pancreatic lymph nodes,⁸⁸ suggesting that their locus of action may be within the islets themselves or locally in the draining nodes. It is not clear how these regulatory populations may be exerting their action. Much interest has centered around the fact that “protective” cells may produce cytokines such as transforming growth factor- β (TGF- β).^{88,89} However, there may be other populations producing cytokines that play a protective role such as IL-10, identified as protective in inflammatory bowel disease.⁹⁰ In addition, it has been suggested that NOD mice may be deficient in a regulatory population of cells, called natural killer (NK) T cells, that produce large quantities of IL-4.^{91–93} This defect has also been reported in BB rats⁹⁴ and suggested in the affected twin of identical twins nonconcordant for diabetes.⁹⁵ Thus the autoimmune process can be viewed as a balance between effector T cells engaged in β -cell destruction and the protecting T cells that are engaged in restraining the effector cells.

These findings are important because they suggest that the outcome of the autoimmune process is determined by the balance between two sets of activatable lymphocytes. If one could artificially activate a set of protective cells, then type 1 diabetes might be prevented, as outlined in the next section. On the other side, how do the attacking cells sustain their attack on tissue in the face of these regulatory influences? This is still poorly understood.

However, one possibility is that the initial attack on a β cell is focused on a single autoantigen. Such responses are relatively easy to regulate, as few T cells are involved, and the process may be terminated at this point. It has been hypothesized that diversification of the autoimmune process is essential for its progression. If diversification outstrips regulation, then disease results; by contrast, the protective influences shut the response down prior to its diversification, they may be dominant. These issues are just beginning to be explored.

IMMUNOLOGIC APPROACHES TO PREVENTION OF TYPE 1 DIABETES

If type 1 diabetes indeed represents an autoimmune T-cell attack on the β cells of the pancreatic islets of Langerhans, as all available evidence suggests, and if disease becomes manifest only after the majority of β -cell mass is lost, then it is clearly crucial that we approach this disease with the idea of preventing its occurrence. Numerous strategies have been suggested for doing this. For instance, immunosuppressive drugs had been advocated in the past, but clinical trials had shown only short-term benefit and the toxicity associated with long-term use of drugs such as cyclosporine A make their use untenable. More recently, various other forms of immunomodulation have been suggested. In the NOD mouse, it had been shown that monoclonal antibodies directed at the T-cell receptor complex—nondepleting anti-CD3 antibodies—were able to reverse diabetes when given after the disease had manifested.^{96,97} This method has been modified to humanize the antibodies and is currently in clinical trial in patients who have very recently been diagnosed with diabetes.

However, it would be even more attractive to prevent disease at a much earlier stage in pathogenesis, before any significant damage is done to the islets. Many different strategies involving administration of putative autoantigens via a number of different routes have shown the ability to protect against diabetes in the NOD mouse.⁴ These are not all applicable in other animal models of diabetes and it is likely that many will not be viable in humans. However, the explanation for the fact that many of these strategies work is the ability to generate cells that have protective qualities. For example, NOD mice have been fed insulin and type 1 diabetes induction was inhibited.^{98,99} This was attributed to the induction of cells producing the cytokine TGF- β . Other studies have used insulin administered nasally, and protection is thought to arise through the generation of another subset of protective T cells known as gamma-delta T cells.¹⁰⁰ It may not be possible to generate protective immunity using antigens that are direct targets of the autoimmune attack because there is no way of knowing when autoimmunity has been initiated. While it is clear that we know much about the generation of protective immunity against pathogens—we have considerable ability to vaccinate to generate immune responses against exogenous (non-self) antigens—much less is known in humans about how to alter or turn off immune responses that are already underway. Alternatively, it may be necessary to generate “bystander suppression” to antigens that are not direct targets of the autoimmune response. This has been shown in principle by the ability to protect against diabetes in the mouse model expressing viral protein in the pancreas that develops diabetes on viral infection.¹⁰¹ In these mice, administration of insulin, but not viral peptides, was able to protect against disease.

One of the major problems associated with all of these approaches is that they require the identification of individuals at risk of developing diabetes. There are two great difficulties associated

with this. First, most cases arise sporadically and not in families, making their identification particularly difficult. Second, our ability to predict which individuals will or will not get T1DM is still very imperfect, even using both genetic and immunologic markers.

The ideal approach would be one that could be given to all of the population, as it avoids the problem of identifying individuals at risk. For this approach to work, it must be inexpensive, essentially nontoxic, and highly effective. Based on the preceding description of the autoimmune process as a balance between attacking and protecting cells, the most likely candidate for prevention of T1DM at the present time is a vaccine that selectively immunizes cells that protect the pancreatic β cells from autoimmune attack. Although this may seem a farfetched goal, the results obtained to date in animal models suggest that targeting an immunologic response to a particular tissue can protect that tissue from autoimmune attack. This does not require a sophisticated analysis of the natural means of protection, as protection appears to be tissue- rather than antigen-specific. A far better understanding of the process by which regulatory immune responses protect target tissues is required before this practice can be made more rational. A reliable means of vaccination against autoimmunity that gives sustained protection would be highly desirable, although whether this can be achieved practically remains to be determined. The ability to identify individuals at risk within families will be crucial to the development of such therapies, as ethical testing of these preventive measures will require their use initially on individuals at high risk of developing T1DM.

SUMMARY

Available data suggest that insulin-dependent diabetes mellitus is an autoimmune disease that targets the β cells of the pancreatic islets of Langerhans. The precise mechanism by which β cells are destroyed in type 1 diabetes is not known, but it clearly involves an adaptive immune response by T lymphocytes. We are beginning to understand how the response is initiated, sustained, and regulated. What is particularly encouraging is the finding that type 1 diabetes is not an unrestrained attack on β cells, but rather involves regulatory influences of T lymphocytes, at least in experimental animal studies. This suggests a potential means of preventing T1DM through the selective activation of these restraining or protective T lymphocytes. The major goal in studying the pathogenesis of T1DM is to understand how the β cells are destroyed and how the process might be specifically inhibited. The latter is clearly the more important goal, as it holds the key to prevention of type 1 diabetes. We envision that disease prevention will require the development of a vaccine to stimulate regulatory cells that protect pancreatic β cells from destruction. This is based on the historic success of immunology in vaccinating specific sets of lymphocytes, and its historic failure to restrain specific responses by immunosuppressive drug therapy. To date, little is known about how the immune response regulates itself, and this is even more true in complex processes like autoimmune diseases. Nevertheless, preliminary studies encourage one to hope that such measures may be available in the future.

Diabetes in Animals: Contribution to the Understanding of Diabetes by Study of Its Etiopathology in Animal Models

Eleazar Shafrir

Animal models of diabetes, guidelines for their use in investigation, and principles for their classification have been outlined in the fourth and fifth editions of this textbook. In the new sixth edition, the information on various forms of animal diabetes is expanded and updated and new species with diabetes are introduced. In discussing the accrued knowledge, emphasis is placed on its relevance to the pathogenesis of human diabetes. The reader interested in animals extensively investigated in the past should consult Chap. 20 of the fourth edition and Chap. 18 of the fifth edition. During recent years some new books and articles on diabetes in animals have appeared,¹⁻⁶ which contain additional information. Table 16-1 summarizes the animals with diabetes in the order that they appear in the text.

DIABETES INDUCED BY CYTOTOXINS SPECIFIC FOR β CELLS

Alloxan, a pyrimidine structurally similar to uric acid and glucose, and streptozocin (STZ), which may be considered glucose with a highly reactive nitrosourea side chain (Fig. 16-1), are selectively toxic to β cells. Their molecular similarity suggests a common site of cytotoxic attack. The elucidation of the mechanism of action of these compounds is important for understanding the destructive processes in β cells in general and for assessing environmental dangers to the endocrine pancreas.

Alloxan

Alloxan is highly unstable in water at neutral pH, but reasonably stable at pH 3. Other uric acid derivatives, dehydrouramil hydrate, 4,5-dihydro-4,5-dihydroxyuric acid, and 5-hydroxypseudouric acid, are also diabetogenic. It has been suggested that alloxan metabolites may be involved in human diabetes; however, no diabetogenic uric acid metabolite has been found in humans except for one report⁷ of increased levels of alloxan in blood from children with type 1 diabetes mellitus (T1DM).

Alloxan is rapidly taken up by β cells and has a direct effect on membrane permeability. Morphologic abnormalities suggest disruption of the β -cell membrane. There is evidence that alloxan acts

at the site of hexose transport, inhibits glucose-stimulated insulin release, and interferes with the generation of glucose-derived energy by inhibiting glycolytic flux and pyruvate oxidation. Both glucose at high concentration and the nonmetabolizable 2-deoxy- and 3-O-methylglucoses, which share the entry site, block the diabetogenic action and restore insulin production.

Malaisse⁸ came to the conclusion that the deleterious effects of alloxan on permeability, transport, intracellular energy generation, and insulin secretion should be attributed to free radical formation. Alloxan is reduced within the cell to dialuric acid, which then autooxidizes to alloxan. Superoxide radicals arise from the alloxan-dialuric acid cycle and are decomposed by the enzyme superoxide dismutase (SOD), producing H_2O_2 . In the presence of Fe^{2+} ions, extremely reactive OH radicals are formed, which can be visualized by chemiluminescence,⁹ and damage various cellular constituents. Pretreatment of cells with SOD, catalase, and a host of nonenzymatic radical scavengers such as NAD or chelators of metal ions protects against alloxan injury.

Boquist¹⁰ provided evidence that alloxan and STZ inhibit enzymes of the tricarboxylic acid cycle and Ca^{2+} -dependent dehydrogenases in β -cell mitochondria, causing ATP deficiency, cessation of insulin production, and cell necrosis. This toxicity mechanism is not an alternative, but rather parallel to that induced by the free radical lesion. This view is supported by Lenzen and coworkers,¹¹⁻¹³ who found that the mitochondrial aconitase and Ca^{2+} transport are inhibited by alloxan, and by the fact that diltiazem, a Ca^{2+} channel blocker, prevents alloxan diabetogenicity. Moreover, pretreatment with verapamil, a Ca^{2+} antagonist, prevents alloxan toxicity and DNA strand breaks by reducing the intracellular influx of Ca^{2+} .¹⁴

Alloxan is most effective after IV injection in a dose of 40–45 mg/kg, producing irreversible β -cell damage within minutes and structural changes within hours in most rodents, dogs, cats, rabbits, monkeys, sheep, cattle, fish, and birds. The response to alloxan may be divided into three phases: (1) initial hyperglycemia lasting ~2 hours, probably due to liver glycogenolysis; (2) transient hypoglycemia at about 6 hours, due to the release of insulin from damaged cells; and (3) permanent hyperglycemia, due to insulin deficiency, setting on after ~12 hours. The hypoglycemic phase may be quite severe and alloxan should not be given to fasted animals.

Several treatments prevent the alloxan-induced β -cell damage *in vivo*, apparently by different mechanisms. Metabolic alkalosis induced with sodium bicarbonate or lactate prior to alloxan injection is protective in rats, but when given after alloxan is not. Diethylthiocarbamate and disulfiram, which induce hyperglycemia, are protective when injected prior to alloxan, and so are glucose, mannose, or fructose, whereas leucine is active both before and immediately after alloxan. The mechanism of glucose protection

is thought to be associated with GLUT-2, the β -cell membrane transporter, and intracellular metabolism. Pretreatment with monomethyl, dimethyl, or monoethylurea, scavengers of OH radicals, completely blocks the action of alloxan, in keeping with *in vitro* observations that inhibition of OH radical formation protects against cellular lesions. Resistance or susceptibility to an alloxan-induced lesion has been observed by Matthews and Leiter^{15,16} in β cells of ALR/LT and ALS/LT mice, respectively, due to genes up- or downregulating the antioxidant cell capacity.

Streptozocin

The diabetogenic action of STZ destroys most islet β cells after a single injection. It is effective in different species-specific doses ranging from 25–200 mg/kg in rats, dogs, mice, hamsters, monkeys, miniature pigs, pigs, and rabbits. It is more effective than alloxan in certain species, such as guinea pig and Syrian hamster, which do not develop permanent hyperglycemia after alloxan. Even among different strains of laboratory rats and mice the effective STZ dose may vary. The variation in susceptibility to STZ appears to be related to the pharmacokinetics of the drug rather than to its direct effect on β cells. STZ-treated animals, though insulinopenic, retain some insulin-secretion capacity, are not ketotic, and do not usually require insulin support for survival. In fact, a mild diabetic state, resembling an insulin-poor type 2 diabetes mellitus (T2DM), may be induced in rats by a single low dose of ~35 mg/kg STZ.¹⁷ However, rats tend to recover spontaneously after receiving doses <35 mg/kg.

STZ is unstable in solution even at acid pH, and should be injected promptly after dissolution in citrate buffer at pH 5.0. Its *in vivo* life span is <15 minutes.¹⁸ As the result of the STZ insult, β cells degranulate but do not completely necrotize, and there is limited proliferation ~4 days after STZ administration to rats. Ductal or acinar cells do not transform into β cells, suggesting that the proliferating cells derive from preexisting precursor β cells.

An impressive body of knowledge on the mechanism of STZ diabetogenicity has been accumulated. Its nitrosourea moiety is responsible for β -cell toxicity, while the deoxyglucose moiety facilitates transport across the cell membrane. The α -anomer of STZ shows higher potency,¹⁹ parallel to the greater effect of the α -glucose anomer on insulin secretion, suggesting the involvement of a membrane glucoreceptor in β -cell penetration. STZ toxicity can be moderated by pretreatment with cortisol, perhaps by augmenting the residual β -cell mass, or by injection of diphenylhydantoin prior to or 60 minutes after STZ. A short-term pretreatment with insulin prevents the STZ diabetogenicity.²⁰

STZ reduces the cellular NAD content in several tissues, and this effect is particularly harmful for β cells as their NAD content is lower than in other tissues.^{21,22} Nicotinamide, the precursor of NAD, protects against STZ diabetes. The NAD depletion is linked to stimulation of the activity of the nuclear enzyme poly (ADP-ribose) synthase, which is involved in the excision and repair of broken DNA strands and requires NAD as substrate. This enzyme is inhibitable by nicotinamide and picolinamide, which prevent the STZ-induced DNA damage *in vivo* and help to maintain the NAD content and insulin biosynthesis *in vitro*. Both STZ and alloxan act by inducing DNA strand breaks first and poly (ADP-ribose) synthase activity subsequently. The profound decline in NAD occurs within minutes after the rise in synthase activity.

A 2-chloroethyl analogue of STZ, chlorotocin, is also diabetogenic and induces DNA strand breaks and DNA–DNA and DNA–

protein crosslinks.²³ Though no islet luminescence can be seen with STZ as with alloxan, the presence of OH radicals can be inferred from the beneficial effect of OH scavengers and/or inhibitors of poly (ADP-ribose) synthase. Nicotinamide exerts considerable protection as late as 2 hours after STZ administration but is effective against alloxan only when given in advance. Poly (ADP-ribose) synthase inhibition alone, without adding OH scavengers, is sufficient to ameliorate STZ diabetogenicity, indicating that the enhanced activity of this enzyme is necessary for the toxic outcome. It is very likely that this action promotes DNA regeneration and the resumption of insulin synthesis. In addition to DNA cleavage by OH radicals, the toxicity of STZ and of its analogue 1-methyl-1-nitrosourea (MNU) also results in alkylation of cell constituents without necessarily being lethal to cells. These nitroso compounds produce highly reactive diazonium and carbonium ions which are able to alkylate and carbamylate, apart from DNA, numerous cytosolic and mitochondrial enzyme proteins vital for energy generation.²⁴ Because STZ produces a steeper fall in NAD than MNU, it is likely that the acute NAD loss is lethal to cells.

Okamoto^{21,22} postulated a uniform mechanism of alloxan and STZ action. This researcher considers fragmentation of β -cell DNA as the crucial event, caused by accumulation of superoxide and OH radicals and DNA alkylation with breaks in DNA strands. This also initiates the processes of excision and repair, involving the activation of poly (ADP-ribose) synthase and the associated NAD depletion. The NAD loss becomes irreplaceable and results in virtual cessation of NAD-dependent energy and protein metabolism, ending in cell necrosis. This unifying concept is supported by preventive effects of nicotinamide and OH scavengers, as mentioned above. Such a mechanism may also apply to other β -cell destructive processes in which there is evidence for generation of free radicals,²⁵ including autoimmune insulinitis due to lymphocyte infiltration.

The likely reasons for the specific β -cell toxicity of alloxan and STZ are: (1) high affinity for the glucose-like moieties related to the exquisite sensitivity of β cells to glucose, raising the concentration of alloxan and STZ to levels higher than in other cells; (2) SH-groups in the β -cell membrane render it especially sensitive to oxidative lesion; (3) β cells have a low capacity for removal of oxidizing radicals due to specific glutathione depletion and low glutathione peroxidase activity^{26,27}; and (4) the NAD:DNA ratio in islets is lower than in other tissues, about one-half of that in the liver.

Another phenomenon associated with STZ diabetes is the high frequency of tumors in pancreatic islets, particularly when the STZ toxicity is mitigated by concomitant administration of nicotinamide or poly (ADP-ribose) synthase inhibitors.^{28,29} Okamoto^{21,22} suggested that the inhibition of DNA repair may cause abnormal DNA recombination, resulting in the formation of tumor-inducing genes. An oncogene was discovered that was expressed in β -cell tumors and was named *rig* for rat insulinoma gene.^{30,31} It is of interest that the same gene was expressed in a BK virus-induced hamster insulinoma and in a spontaneous human insulinoma.^{21,31}

The discovery of an oncogene that may be unique to β cells appearing subsequent to prevention of cytotoxic assault led to the study of β -cell replication in pancreatectomized rats. This diabetes model is characterized by an exhaustion of insulin production, together with marked hypertrophy of the remaining islets. When these rats receive poly (ADP-ribose) synthase inhibitors starting 7 days before pancreatectomy, the glucosuria and glucose tolerance improve, islet hypertrophy is reduced, and the granulated β -cell

mass increases in the pancreas remnant, compared with pancreatectomized nontreated rats. Okamoto^{21,22} constructed from pancreas remnants a poly (A)⁺RNA-derived cDNA library and isolated a *reg* (regeneration) gene. The *reg* gene is expressed only in islets of pancreatectomized, nicotinamide-treated rats, and is not present in control islets or in regenerating liver, brain, kidneys, or insulinoma. The *reg* gene, probably specifically regulating β -cell proliferation, was also isolated from hyperplastic islets of glucose-thioglucose-treated NON mice (described later) and a *reg* homologue was found in the human pancreas. The *reg* gene has been cloned and shown to induce β -cell replication in cultured islets in the pancreas remnant of pancreatectomized rats.³²

METABOLIC AND ENDOCRINE CHANGES IN ALLOXAN- AND STZ-DIABETIC ANIMALS

Glucose Metabolism

Hepatic glucose production and the activity of the rate-limiting enzyme phosphoenolpyruvate carboxykinase (PEPCK) are increased because of lack of control in the virtual absence of insulin. Reduced glucose utilization and lipogenesis are typical outcomes in insulinopenic diabetes induced either by alloxan or STZ. This is due to well-documented inhibition of expression of regulatory enzymes of glycolysis and lipogenesis and not to a direct effect of the toxins. An increased flow of glucogenic precursors, such as lactate, alanine or glycerol, from muscle and adipose tissue elevates the hepatic glucose production.

Similarly, changes typical of the absence of insulin are evident in glycogenolysis and glycogenesis through the effects of interconversion of active-inactive forms of glycogen synthase and phosphorylase in the direction favoring glycogen breakdown. A characteristic outcome is the subnormal hepatic glycogen concentration in the fed state and higher than control levels in the fasting state. In several insulin-independent tissues glycogen paradoxically accumulates (kidney, intestine, and placenta).^{33,34} This is related to intracellular accumulation of glucose-6-phosphate, an allosteric activator of glycogen synthase in the absence of insulin.

Increased intestinal mass and nutrient absorption are typical of diabetic hyperphagia, evident in STZ- and alloxan-treated rats. There is an elevation in the intestinal brush border membrane hydrolases active in hexose transport. This may result from enhanced specific enzyme synthesis, or intestinal proliferation, or both. There is an overexpression of intestinal GLUT-2 and GLUT-5.³⁵

Protein Metabolism

Alloxan- and STZ-diabetic animals have a negative nitrogen balance related to enhanced proteolysis in muscles and other tissues and to reduced protein synthesis. Growth failure is also due to the reduced production of growth factors and increased growth factor binding protein.³⁶⁻³⁸ Proteolysis is effected both by a rapid mechanism and a slow, long-lasting activation of a myofibrillar protease which is only gradually abolished by insulin.^{39,40} The STZ-induced diabetes results in the decrease of collagen synthesis, which exceeds the negative total protein balance in the muscle.⁴¹ Protein catabolism and flow of amino acids to the liver feed the gluconeogenic pathway and accelerate ureagenesis. STZ diabetes

associated with partial loss of hepatic endoplasmic reticulum and of lysosomes, probably related to the enhanced autophagia.⁴²

Lipid Metabolism

Alloxan- and STZ-diabetic rats excessively mobilize free fatty acids (FFAs) due to the rise in adipose tissue lipase activity with resultant vigorous muscle and liver FFA oxidation. The activity of carnitine acyl CoA transferase, regulating the transport of fatty acids into the mitochondria, is elevated in rat liver and kidney, whereas the concentration of malonyl CoA, the regulator of acyl CoA entry into mitochondria, is lowered.⁴³ This is less evident in obese rats. They are also characterized by elevated FFA transport, but their hyperinsulinemia abrogates fat oxidation. In diabetic animals the ratio of FFA oxidation to esterification is double that of nondiabetic animals.⁴⁴ Ketosis is present more often in alloxan- than in STZ-diabetic animals, but does not usually progress to ketoacidosis. This is an important distinction from rats and mice with autoimmune type 1-like diabetes, and indicates that insulin secretion from residual or regenerated β cells prevents an unrestrained FFA mobilization with lapse into ketosis. This "spontaneous" amelioration of diabetes limits the period of severe insulin deficiency in STZ- or alloxan-treated animals to a few weeks after the induction of diabetes, and requires scrutiny of β -cell function for long-term experiments.

An elevation in plasma triglycerides, cholesterol, and phospholipids in the VLDL and LDL fractions is evident in diabetic animals, due in part to the hepatic recirculation of inflowing FFAs and other lipids and to the delayed disposal of VLDL and chylomicrons. This is related to decreases in the translation and activity of insulin-dependent lipoprotein lipase (LPL) and in the apoprotein moieties of lipoproteins,⁴⁵⁻⁴⁸ necessary for the recognition and activation of uptake of the triglyceride-rich particles. It should be emphasized that the HDL fraction is also increased in insulinopenic rodents, in contrast to humans, because HDL functions in both forward and reverse transport of cholesterol in rodents.

Although diabetic animals manifest hypercholesterolemia and atherosclerosis,⁴⁸ the hepatic synthesis of cholesterol is either reduced or unchanged.⁴⁹ There is evidence for inhibited liver HMG CoA reductase, the rate-limiting enzyme of cholesterol synthesis.⁵⁰ Conversely, there is a rise in intestinal synthesis of cholesterol due both to a specific increase and tissue proliferation related to hyperphagia.^{49,51} Thus diabetic hypercholesterolemia is mainly of intestinal origin and may be the reason for suppression of hepatic cholesterol production.

Insulin Receptor and Endocrine Derangements

Alloxan- and STZ-diabetic animals excessively secrete somatostatin. Also, arginine- and glucose-induced somatostatin release from isolated rat pancreas is enhanced^{52,53} as islet δ cells are not affected. However, the glucose-stimulated islets of STZ-diabetic dogs fail to respond with increased somatostatin and decreased glucagon secretion, whereas the responses to arginine and isoproterenol are normal,⁵⁴ suggesting either the blunting of glucose recognition by δ and α cells or compensation by hyperglycemia. Shortly after STZ injection, the basal and stimulated secretion of glucagon is enhanced in rats, but suppressed by exogenous insulin. This suggests that the glucagonemia and somatostatinemia that occur in insulinopenic animals are a consequence of β -cell loss.

With regard to the low fertility of diabetic animals, extensive functional and morphologic neuroendocrine degenerative alter-

ations have been found in the mediobasal hypothalamus of STZ-treated rats.⁵⁵ The lesions, affecting luteinizing hormone-releasing hormone synthesis and secretion, were attributed to the direct, local effect of hypoinsulinemia. The reduced neurohormone release from the exhausted pool seems responsible for the wasting of pituitary gonadotrophs and the resulting hypofunction of the pituitary-gonadal hormone axis. There is also evidence of attenuated feedback control of LH release in STZ diabetes⁵⁶ and lack of the response of the ovary to FSH in alloxan diabetes, related to atresia shortly after the induction of alloxan diabetes.⁵⁷

Insulin receptors in models of insulinopenic diabetes bind insulin well in adipocytes, hepatocytes, and muscle, in contrast to animals with hyperinsulinemia and insulin resistance, which generally show downregulation of insulin binding and reduced activity of the insulin receptor tyrosine kinase (TK).⁵⁸ The increased binding in STZ-treated animals is mainly due to recruitment of receptors and not to higher affinity⁵⁹ except in severely diabetic rats.⁶⁰ Notwithstanding the increased binding, the activity of hepatic TK per receptor is either reduced or unchanged.⁵⁸ However, the TK activity is markedly stimulated after contact with insulin, and total TK receptor autophosphorylation is elevated in muscle and liver, but is not increased per receptor.⁶¹ It is possible that multisite phosphorylation occurs in the presence of added insulin, involving serine/threonine residues on the receptor,⁶² which is inhibitory to TK-mediated phosphorylation. It could also be due to increased phosphotyrosine phosphatase activity in diabetic rats.⁶³ In any case, a relative reduction in phosphorylation in the face of increased insulin binding and receptor number upregulation seems to characterize insulinopenic animals. A similar change was demonstrated in severely insulin-deprived BB rats.⁶⁴

Drug metabolism is altered in insulinopenic diabetes. Microsomal P-450 cytochrome-dependent enzymes (such as aniline hydroxylase and monooxygenase activities) exhibit increased mRNA levels and activity, which may be reversed by insulin treatment.⁶⁵ This enhanced capacity of the liver to detoxify xenobiotics may in some cases not be advantageous, as genotoxic intermediates can be formed and the diabetic organism may be susceptible to the toxicity or oncogenicity of such chemicals.⁶⁶

DIABETES ELICITED BY LOW, MULTIPLE DOSES OF STREPTOZOCIN (MD-STZ)

Repeated small doses of STZ, insufficient for immediate diabetogenesis, produce in susceptible species a delayed insulinitis-related diabetes. Like and Rossini⁶⁷ observed that 200 mg/kg STZ, given to male CD-1 mice in five consecutive daily doses of 40 mg/kg, causes hyperglycemia within 1-2 weeks. A lymphocytic islet infiltration results, preventable by rabbit antiserum against mouse lymphocytes (ALS), suggesting an inflammatory, possibly an autoimmune, reaction. 3-O-methylglucose or nicotinamide, which protects against a single β -cell necrotizing STZ dose, also reduces the MD-STZ syndrome. MD-STZ diabetes is prevented by glucose or 5-thiogluconate given before STZ injection or added with STZ to β -cell cultures *in vitro*.⁶⁸ Although the hyperglycemia is fully prevented, attesting to the protection of the insulin-secreting apparatus, the inflammatory response is not. This points to dissociation between insulinitis and β -cell destruction. Preservation of β -cell integrity by the above-mentioned and other treatments⁶⁹ supports the view that the injury may be due to a combination of cell-mediated autoimmunity and a metabolic, glucose-dependent lesion.

Kolb and associates^{69,70} gathered support for a T-cell-mediated mechanism of insulinitis. Athymic nude mice, which are less responsive to MD-STZ, fail to show islet lymphocyte infiltration, but when grafted with thymus exhibit the full syndrome. Numerous immunomodulators prevent the syndrome. Silica, a macrophage toxin, also prevents the induction of MD-STZ diabetes, implying a role for cellular immune mechanisms. However, questions remain whether insulinitis is causal or only associated with cell death. Treatment of mice with dimethylurea, an OH scavenger, prior to MD-STZ protects against the hyperglycemia but not against insulinitis. When dimethylurea is employed to prevent the high-dose STZ diabetes, delayed hyperglycemia and insulinitis may occur instead. Evidence has been provided⁷¹ that the type 1 diabetes-like syndrome induced by MD-STZ is not due to the autoimmune T- or B-lymphocyte-mediated mechanisms occurring in NOD mice. When MD-STZ was administered to severely immunodeficient male (*scid/scid*) NOD mice, which are devoid of functional lymphocytes, even low STZ doses of 30 mg/kg induced hyperglycemia without insulinitis.

As reviewed by Wilson and Leiter,⁷² male C57BKS mice, which are highly sensitive to the induction of both insulinitis and hyperglycemia, also show an induction of retroviral genome, such as intracisternal type A and C virus particles in islets, 2 days prior to insulinitis. The presence of "silent" viruses in mice islets appears to be frequent, and the possibility that STZ activates some of them, with consequent alteration in islet antigenicity, cannot be ruled out. However, it is certain that MD-STZ mice represent a diabetic condition produced by an exogenous toxin and that this model is distinct from that underlying autoimmune human T1DM. Nevertheless, the MD-STZ model is important for gaining insight into structural and genetic lesions in β cells.

ANIMALS WITH AUTOIMMUNE ETIOLOGY AND INSULIN DEPENDENCE

The discovery of two animal species with spontaneous autoimmune diabetes, BB rats and NOD mice, contributed to the general acceptance of the etiologic role of autoimmunity in T1DM.

The BB Rat

The major features of the syndrome in BB rats in its pathogenic phase are described here. More details on history, husbandry, and complications can be found in special review publications⁷³⁻⁷⁵ (see Chap. 20). The classic symptoms of weight loss, polyuria, polydipsia, glucosuria, and ketoacidosis appear abruptly with marked hyperglycemia, hypoinsulinemia, insulinitis, and β -cell loss. The diabetes-prone rats may show IGT a few days before the onset of overt symptoms at 60–120 days of age. Levels of islet insulin become very low, and most diabetic animals are totally insulin dependent for survival within a few days. Several sublines varying in frequency, severity, immunologic characteristics, and time of diabetes onset are available, including three diabetes-resistant lines in which <1% of animals become diabetic.⁷⁵

Breeding of BB rats requires great care because of their lymphopenia, vulnerability to infections, and the need for individual supervision and insulin treatment. As variations in the incidence and expression of diabetes upon exposure to viral or microbial pathogens in various localities occur in BB rats,^{76,77} it has been

agreed to denote their derivation by a slash following the BB designation (BB/Wor for the Worcester colony and BB/O for the Ontario colony). Of the inbred BB/Wor rats, the source of seven worldwide colonies, 50–80% become diabetic; males and females are equally affected.

The diabetes in BB/Wor rats is probably inherited by autosomal recessive transmission, with about 50% penetrance related to at least two genes. One non-MHC linked gene expresses the T-cell lymphopenia; the second is linked with RT¹, the MHC of the rat. This resembles human T1DM without association with specific HLA types. However, subsequent investigations indicate that the permissive MHC haplotype and the recessive lymphopenic gene are not specifically related to diabetes and are insufficient to produce diabetes susceptibility in the BB rat.⁷⁹ Although BB rats share the class II RT1^u rat MHC, they are not all genetically identical. Genetic heterogeneity of the BB rat has been investigated among 26 distinct lines, analyzing 19 protein markers.⁸⁰ Polymorphism in nine markers has been observed and used to define seven distinct haplotypes. Therefore, interpretation of genetic, immune, and metabolic investigations of BB rats should take into account their origin and maintenance of the colonies from which the animals were derived.

Pancreas histology immediately after the outset of hyperglycemia shows a striking lymphocytic islet infiltration (Fig. 16-2). Insulinitis precedes the onset of overt diabetes by several days and

FIGURE 16-2. Insulinitis in the NOD mouse. **A.** Peripheral accumulation of mononuclear lymphocytes with yet functional β cells. **B.** Penetration of mononuclear lymphocytes into the islet with destruction of β cells. A

B

disappears after β -cell loss, leaving shrunken end-stage islets composed almost entirely of α , δ , and PP cells. Insulinitis to a varying extent is also observed in 50–75% of nonhyperglycemic BB/Wor rats. Nitric oxide is a probable β -cell cytotoxic agent. The inducible NO synthase (iNOS) has been found in the pancreas of BB rats with insulinitis by RT-PCR and immunohistochemistry.^{81,82} iNOS expression was limited to areas of islet infiltration by macrophages, and produced by macrophages, suggesting iNOS involvement in islet destruction⁸¹ in genetic association with T lymphopenia.⁸³

The autoimmune syndrome of BB rats is polyendocrine in nature, as evident from the frequent occurrence of lymphocytic thyroiditis and of autoantibodies against smooth and skeletal muscle, gastric parietal cells, thyroglobulin, and thyroid cells. Islet cell cytoplasmic antibodies (ICAs), thought to arise from cellular constituents after degradation, and islet cell surface antibodies (ICSAs), formed against specific cell membrane components, are often present in the circulation. Although it is known that not all animals with antibodies develop diabetes and not all animals with diabetes carry antibodies, a careful correlation of circulating antibodies with insulinitis and diabetes in BB/Wor and BB/O strains reveals that they are more frequent in diabetes-prone than in diabetes-resistant BB rats and are often present at weaning.⁸⁴

Among the features of BB rats resembling human T1DM is the prepubertal onset with a silent prediabetic period, which presents an opportunity for the search for early markers of the disorder. Plasma lymphocyte antibodies⁸⁵ and bioprotein, released by macrophages upon cytokine activation,⁸⁶ have been proposed as predictors. Avoidance of certain wheat- and milk-derived dietary proteins^{87–89} was suggested as beneficial for delaying or preventing the expression of diabetes in BB rats and humans. Acividin, the inhibitor of glutamine metabolism, prevents BB rat diabetes, possibly by interacting with the activated insulinitis-producing lymphocytes.⁹⁰

The detection of ICSAs 1–2 months before the onset of diabetes in BB rats parallels their early presence in prediabetic children and their association with islet destruction. However, decisive proof of a direct pathogenic role of ICSAs *in vivo* is still lacking despite correlations between the start of mononuclear islet infiltration and diabetes onset, and between the appearance of complement-fixing ICSAs and β -cell destruction. ICAs have not been conclusively found in BB rats.⁷⁴ Moreover, GAD antibodies considered important for the prediction of human T1DM are absent in some lines of BB rats,^{91–93} but have been detected in the BB/O line.⁹⁴ Also, IA-2 antibodies have been detected in some lines, but not in others.⁹⁵

There is at least one notable difference between the BB rat and human diabetes. The severe generalized lymphopenia occurring in the former, which precedes clinical manifestations of diabetes, involves both primary and secondary lymphoid tissues and affects all subsets of T cells. The T-cell lymphopenia is permissive rather than obligatory for diabetes to occur.⁹⁶ It is uniformly present in all diabetes-prone and diabetic BB/Wor rats, and is suggested to originate from a hematopoietic stem cell defect, or from a defective thymic maturation process.⁷⁵ All inbred, diabetes-prone BB/Wor rats appear to have reduced phenotypic and functional cytolytic T cells and a lack of RT6⁺ cells. These defects are absent in diabetes-resistant BB/Wor rats. Although the progression of the lymphocytic infiltration as an intermediate stage of β -cell destruction is now better understood, the initial events remain obscure. The role of lymphopenia and of the involved subsets has yet to be ascertained, as diabetes occurs without lymphopenia in the inbred, re-

sistant BB/Wor lines and in diabetes-prone NOD mice. An alteration of islet β -cell antigenicity is possible, which may result in activation of T lymphocytes, NK cells, and cytotoxic antibodies directed against β cells. The nature and interaction of the humoral antibodies and cell antigens remain to be elucidated. In this respect, it is intriguing that a membrane-bound islet-specific 38-kD autoantigen⁹⁷ becomes expressed in diabetes-prone BB rats at 30 days of age, when the immune effectors start to recognize β cells. The delayed expression may be crucial for effecting the breakdown of self-tolerance and for initiating autoimmunity. Another promising aspect of this increasingly immunologic rather than diabetologic discipline is immunomodulation.⁷⁵ In BB rats, not only are the various β cell-destroying effectors present at the onset of diabetes, but the regulatory T cells, which control the system, are defective or missing. These may be RT6⁺ postthymic lymphocytes (carrying the RT6 rat alloantigen), detectable in peripheral lymphocytes of diabetes-resistant BB rats but missing in the diabetes-prone line. Removal of the RT6⁺ cells in the former with a monoclonal antibody frequently induces insulinitis, and renders them diabetic, and their splenocytes are capable of transferring the disease to nondiabetic BB rats. Immunomodulatory interventions may entail changing the balance between subsets of T lymphocytes by cyclophosphamide, or stimulation of lymphopoiesis by blood removal, dietary changes, and immunogenic stimulation.⁷⁵

The Nonobese Diabetic (NOD) Mouse

A large body of information on the development, pathophysiology, immunopathogenesis, and genetics of NOD mice is now available in reviews.^{98–102} The NOD mice were raised in Japan in the late 1960s by inbreeding a single female glucosuric mouse from a substrain of ICR mice, and are now distributed worldwide. Their salient feature is the spontaneous lymphocytic islet infiltration, starting at the age of 4–5 weeks, that leads to overt diabetes at 13–30 weeks, with severe hyperglycemia and both plasma and β -cell insulin deficiency. Unlike BB rats they do not become ketoacidotic, but require maintenance on insulin. Insulinitis is prevalent both in males and females at 5 weeks, but in the original colony overt diabetes occurs in 80% of females and in only 20% of males at 30 weeks. However, the lines established outside the original colony at Shionogi Laboratories in Japan differ in diabetes incidence, time of onset, and gender ratio.

The lymphocytes infiltrating the islets include CD4⁺ and CD8⁺ T cells and B cells. The insulinitis differs somewhat from that in the BB rats.^{103,104} In the initial invasion stage, the lymphocytes are localized in the periductular capillary spaces with a clear basement membrane boundary without overt contact with the β cells. Later, the lymphocytes invade the islet; β cells are destroyed, but α , δ , and PP cells remain intact. Unlike the pronounced lymphopenia of BB rats, NOD mice exhibit little or no lymphocyte decline. Antibodies directed toward a variety of islet antigens, including GAD, are detectable soon after weaning and ICSAs at 6 weeks, with 50% prevalence between 12 and 18 weeks.

The NOD model is important for the understanding of conditions predisposing to T1DM. Although the contribution of multiple genes on different chromosomes to diabetes susceptibility has been demonstrated,^{103–108} the environmental, nutritional, and hormonal impact on the incidence of diabetes, despite the identical genetic background, affects the penetrance of genetic susceptibility. For example, the incidence of diabetes in males may vary from 0–100%. Castration of males increases the incidence of diabetes,

whereas implantation of testosterone to young females prevents diabetes, apparently by inhibiting the production or function of autoimmune effectors. This suggests that the gender dimorphism has a genetic background, possibly due to hormonal imprinting early in life, but its expression is amenable to manipulation.

It is striking that the exposure of NOD mice to murine viral pathogens protects against diabetes, probably through general immunostimulation, because several exogenous immunomodulators, such as complete Freund's adjuvant, various cytokines, poly I:C, or gangliosides, also prevent or attenuate the diabetes development, as reviewed by Kolb.⁶⁹ These effects are more marked in NOD mice than in BB rats. All these factors are also responsible for the continuing genetic drift in various colonies, which must be considered when analyzing and comparing the experimental results from various sources. To facilitate evaluations, the inbred substrains should be labeled by adding a suffix after a slash (NOD/Shi for the Shionogi colony or NOD/Lt for the Jackson colony).

In contrast to BB rats, the β -cell deterioration in NOD mice is markedly attenuated by nicotinamide, scavengers of free radicals, and inhibitors of poly (ADP-ribose) synthase.²¹ Thus, the destructive processes show more similarities to the action of chemical cytotoxins in NOD mice than in BB rats, although these differences may be quantitative in nature. It is of interest that, as in the BB rat, pretreatment with insulin prevents the adoptive transfer of diabetes.¹⁰⁹ The different aspects of human T1DM are compared to those in BB rats and NOD mice in Table 16-2.

Although most investigations of the origin of NOD diabetes have focused on T lymphocytes as effectors, there is strong evidence that functional defects in bone marrow-derived antigen-presenting cells (APCs) may be responsible for the appearance of β -cell autoreactive T lymphocytes. This is based on observations that diabetogenic T lymphocytes become active in diabetes-

resistant hybrid NOD strains that are lethally irradiated and transplanted with nonhybrid NOD bone marrow.^{110,111} APCs determine the spectrum of the T-cell repertoire by carrying self-antigens in the thymus. Ineffective presentation of antigens by APCs may cause their faulty tolerogenic functions such as the inability to activate functional immunoregulatory T (suppressor) cells in the periphery and to block the thymic development of autoreactive lymphocytes against islet β cells.

The LETL Rat

The Long Evans Tokushima Lean (LETL) spontaneously diabetic strain of rats was isolated in the 1980s in Japan, from a colony based on a few pairs of outbred Long Evans rats.¹¹² The diabetes onset in inbred animals occurs at 8–20 weeks of age with an average incidence of 21% in males and 15% in females, influenced by whether one or two parents were diabetic. The incidence of diabetes at 16 weeks of age is doubled by pretreatment with cyclophosphamide, starting at 5–7 weeks.¹¹³ The clinical features of diabetes are typical of type 1 diabetes and the LETL rats require insulin for survival. A control LETO strain which exhibits type 2 diabetes, was inbred from nondiabetic animals of the same stock.

In contrast to BB rats, the LETL rats are not lymphopenic and the distribution of the thymocyte subsets is similar to that of control rats. A marked lymphocytic infiltration of islets occurs 4 days before the onset of clinical diabetes. Insulinitis is not observed in nondiabetic siblings and in the LETO control line. Lymphocytic infiltration occurs in other glands, similarly to the polyendocrine character of the disease in BB rats and NOD mice. With regard to genetics, the LETL rats carry the RT1^u haplotype, as does the diabetes-prone BB rat. At least two recessive genes, one closely linked with RT1^u, seem to be involved in the pathogenesis of insulinitis.

TABLE 16-2 Characteristics of Autoimmune (Type 1) Diabetes in Humans, NOD Mice, and BB Rats

	Humans	NOD Mice	BB Rats
Hyperglycemia, insulinopenia	+	+	+
Ketoacidosis (if untreated)	+	—	+
Female over male gender bias	—	+	—

Two new animal with spontaneous autoimmune etiology, which provide new perspective in the clarification of the autoimmune mechanisms, have recently been reported upon. The **Torri rat** of the Sprague Dawley strain manifested an incidence of diabetes of 100% in males and 33% in females at 45 weeks of age.¹¹⁴ Hyperglycemia, hypoinsulinemia and hyperlipidemia were present at 25 weeks with marked fibrosis of pancreatic islets. Torri rats were characterized by long-term survival without insulin support. The particular characteristics are severe ocular complications, cataract and retinopathy with tractional, retinal detachment, fibrous proliferation and massive hemorrhage at 70–77 weeks of age.

The **LEW.IAR1/Ztm-iddm rat** also exhibits T1DM arising from spontaneous mutation in congenic Lewis rat strain with a defined MHC haplotype.¹¹⁵ The incidence of T1DM was 20% without sex preference at 8–9 weeks. The proportion of T lymphocytes in the peripheral blood was normal expressing the RT6.1 differentiation antigen. Islets were heavily infiltrated with both T and B lymphocytes, macrophages and NK cells. Apoptotic cell death was evident in the areas of insulinitis.

GENETICALLY ALTERED ANIMALS FOR DIABETES RESEARCH

Transgenic and gene-disrupted animals, mainly mice, represent a rapidly expanding technological advance in diabetes research made possible by the ability to introduce transgenes or delete existing genes. These mice are not in a strict sense models of diabetes, but manipulating their genetic expression provides valuable information on the *in vivo* function of a particular gene to assess its role in pathophysiology of diabetes (e.g., glucose transport, insulinogenesis, cell replication, or autoimmunity).

It is beyond the scope of this chapter to overview the plethora of transgenic mice that have been recently investigated. Just a mention of several examples is possible. One of the early studies using transgenic constructs was the implantation of a hybrid insulin oncogene SV40 T antigen (*Tag*) to direct the expression of specific proteins in islet β cells.^{116,117} The hybrid-injected eggs were then placed in the oviducts of pseudopregnant female mice, which led to the development of insulinoma. Rat insulin promoter (RIP-*Tag*) lines have been obtained that vary in their progression to a tumor. These experiments were intended to create insulin-producing cells capable of proliferation at a controlled rate.

Insulin has been overexpressed in β cells with multiple copies of the human insulin gene. These mice manifested a profuse insulin secretion leading to insulin resistance and downregulation of tissue insulin receptors.¹¹⁸ This illustrates the detrimental effect of insulin excess on receptor number and function typical of type 2-like diabetes. Another transgenic model of a type 2 diabetic condition has been produced by expressing a component of the human insulin receptor with high-affinity insulin binding.¹¹⁹ In this situation postabsorptive hyperglycemia and hepatic gluconeogenesis ensue despite hyperinsulinemia. Transgenic mice overproducing islet amyloid polypeptide were also prepared, showing an associated insulin storage and increased cosecretion, and eventually amyloid deposits on a high-fat diet.¹²⁰

The glucokinase gene has been overexpressed in the liver to correct the hyperglycemia of type 1 diabetes.^{121,122} A phenotype with increased hepatic glycogen content, hypoglycemia, and hypoinsulinemia was obtained. Suppression of the promoter gene

driving the insulin-dependent PEPCK in the liver was carried out to reduce the hepatic glucose production in diabetic mice.^{123,124}

The selective disruption of the insulin receptor substrate-1 (IRS-1) substrate of the insulin receptor tyrosine kinase has, surprisingly, produced only mild insulin resistance.^{125,126} The overexpression of the GLUT-4 gene in several transgenic mouse models resulted in fasting hypoglycemia and hypoinsulinemia due to overutilization of glucose in peripheral tissues.^{127,128} The negative result of this hypoinsulinemia was enhanced lipolysis with elevation of plasma triglycerides and ketosis. In general, transgenic animals demonstrated that the GLUT-4 level controls the rate of overall glucose metabolism, particularly in skeletal muscle. Hexokinase II becomes rate limiting only under conditions of hyperglycemia with hypoinsulinemia. Insulin action is correlated with the amount of GLUT-4 protein. Thus the improvement in IGT can be effected by a regulated overexpression of a single protein.^{129,130} Severe hyperglycemia and insulin resistance in *db/db* mice were considerably ameliorated by overexpression of GLUT-4.¹³¹ Additional examples of transgenic mice in the study of various aspects of diabetes are listed in reviews.^{132,133}

INSULIN-RESISTANT, MUTANT RODENTS WITH DIABESITY

db/db Mice with Hyperinsulinemia, Insulin Resistance, and Hyperglycemia Leading to β -Cell Collapse, Now Labeled as *lepr^{db}*

The mutation designated as *db* occurred spontaneously in the C57BL/Ks inbred strain of mice in Bar Harbor, Maine.^{134,135} Diabetes in the *db/db* mice is a recessive, autosomal single-gene mutation on chromosome 4, with complete penetrance. It is now considered to be the homologue of the rat *fa* gene on chromosome 5 and its allele corpulent *cp* (described later). The *db* gene has been linked to the black coat misty gene on chromosome 4, which allows early identification of homozygotes in congenic *mdb* strains. Homozygous *db/db* mice are infertile, so heterozygous *db/+* carriers are used to breed the mutants. The *db* gene manifests different expressions on BL/6J and BL/Ks backgrounds. The diabetes is mild and resembles the *ob* mutation on the BL/6J background. In contrast, the Ks background imparts a marked insulin resistance and ketosis and glucose overproduction, associated with marked damage to the insulin secretion apparatus and eventual death in the face of massive glycemia.^{134,135} This is a cogent illustration of the impact of deleterious genomic modifiers on the course, severity, and final outcome of the diabetes syndrome (the interrelation of obesity and diabetes, discussed later) caused by a single abnormal gene.

As outlined in Table 16-3, the initial stages of the syndrome are characterized by hyperphagia and hyperinsulinemia at the time of weaning. The mice gain weight and become hyperglycemic [up to 400 mg/dL (33 mmol/L)] between 8 and 12 weeks, in spite of 6- to 10-fold higher than normal insulin levels. At 3–6 months, the insulinemia wanes to subnormal levels, β -cell secretion ceases, and the mice become ketotic with β -cell necrosis and do not survive longer than 10 months. Shifts in the time course of diabetes development may occur in *db/db* mice raised in other colonies, and investigators should establish their own local reference values.

Consistent with hyperglycemia and hyperinsulinemia as the earliest abnormalities in *db/db* mice, the β -cell insulin oversecre-

TABLE 16-3 Genetically Predetermined Time Course of Diabetes Development and Progress in C57BL/KS *db/db* (*lepr^{db}*) Mice Maintained on Regular Diet*

Stage B <1 month old	Stage C 2–3 months old	Stage D >3 months old	Stage E 8–10 months old
Hyperinsulinemia	Peak insulinemia	Hypoinsulinemia	Severely insulin-deficient, almost complete β -cell loss
Normoglycemia	Hyperglycemia	Marked hyperglycemia	Ketosis
Hyperphagia	Hyperphagia	Hyperphagia	Hyperphagia
Moderate weight gain	Marked weight gain	Weight loss	Leanness
Mild insulin resistance	High gluconeogenesis and lipogenesis	High gluconeogenesis	No survival beyond this age
		Severe β -cell degranulation	

*Because there are no nondiabetic *db/db* mutants, stage A (reference) designation is reserved for the normoinsulinemic-normoglycemic heterozygote siblings.

tion lasts up to 4 months irrespective of the islet content. The reduced β -cell response to glucose, but sustained response to arginine, occurs concurrently with a loss of the β -cell GLUT-2 transporter. This is a reversible phenomenon, because *db* islets transplanted to nondiabetic *db/+* controls regain GLUT-2 expression.¹³⁶ At the phase of reduced insulin secretion there are ultrastructural changes comprised of dilatation of Golgi apparatus and of rough endoplasmic reticulum.¹³⁷ Incorporation of ³H-leucine into insulin indicates first an increased synthesis in young mice, and then a decline concomitant with changes in insulin release. Similar findings were obtained with ³H-thymidine incorporation. β -Cell polyploidy, involving the DNA,¹³⁸ enlargement of the islets, and hypertrophy of individual cells, suggests mobilization of β -cell precursors. Although insulin oversecretion initially compensates for the insulin resistance, β cells are unable to sustain the high secretion rate. The end-stage necrosis is drastic, leaving atrophied islets with δ , α , and PP cells only.

Tissue insulin resistance in young *db/db* mice is demonstrated by low response to injected insulin or to implanted islets from isogenic donors.^{134,135} Insulin treatment does not appreciably influence the progression to diabetes. In the young mice, the glycolytic enzymes and glucose oxidation are enhanced by insulin induction, as would be expected. In older, hyperglycemic mice, the activity of glycolytic enzymes declines, while the gluconeogenic pathway escapes control, despite the high concentration of circulating insulin. PEPCK synthesis, assessed by hepatic PEPCK mRNA levels, is normally reduced by physiologic rises in circulating insulin, but suppression of its activity and transcription in *db/db* mice requires enormous amounts of exogenous insulin.¹³⁹ Regulatory failure of other liver systems is also evident. Glycogen breakdown proceeds at an accelerated rate and is not inhibited by glucose, as occurs normally. Interestingly, the hepatic insulin resistance does not affect lipogenic enzymes, which remain responsive to insulin and rise in activity, accounting for the prevalent hyperlipidemia in diabetic *db/db* mice. Enhanced lipogenesis is also expressed in the small intestine.¹⁴⁰

Insulin resistance is evident by reduced insulin binding to receptors and reduced receptor tyrosine kinase activity in muscle, liver, and isolated fibroblasts.^{141,142} Adipose tissue of young mice exhibits increased glycolysis and undiminished insulin response. In older mice, an inverse pattern of stimulated FFA outflow reflects insensitivity of adipose tissue lipolysis to insulin.

Dietary restriction does not induce normoinsulinemia in *db/db* mice. Total substitution of protein for carbohydrate has a marked

beneficial effect.¹⁴³ The regimen of 83% casein does substantially reduce the insulin resistance and hyperglycemia. It also extends the life span, retards the decrease in islet insulin content,¹³⁹ and delays β -cell necrosis, most likely through the alleviation of glucotoxicity. Inclusion of even 8% of carbohydrate in the diet, particularly sucrose, substantially aggravates the diabetes and shortens the life span of these mice. The high-protein diet diminishes the glycemia by making it dependent on endogenously regulated hepatic gluconeogenesis in the absence of intestinally absorbed glucose.

Hypothalamic disturbance is evident in *db/db* mice, manifested by early hyperphagia, insulin secretion, and obesity. The mice fail to respond to satiety signals. Coleman and Hummel impressively demonstrated this by parabiosis with nondiabetic mice.¹⁴⁴ The latter stop eating and starve to death within 2–4 weeks, due to an exaggerated response to the inflow of satiety factors from *db/db* mice now known to be leptin. The *db/db* mice gained weight and did not respond to their own satiety factor or to that of nondiabetic mice because of the defect in the hypothalamic leptin receptor, now known to be a truncation mutation.

Striking results were obtained when *db/db* mice were parabiosed with congenic *ob/ob* partners.¹⁴⁵ The latter stopped eating, became lean, and died from starvation because of the response to the massive inflow of the satiety factor leptin, which they normally lacked. When *ob/ob* mice are parabiosed with normal mice, they lose weight themselves, showing that their own satiety systems react appropriately to leptin.

It took about 20 years to provide the molecular basis for the prescient hypothesis of Coleman about the nature of *db* and *ob* mutations through isolation by Friedman and Halaas of the *ob* gene product leptin¹⁴⁷ and by others of the leptin receptor.^{146,148} This discovery provided an explanation for the defects seen in *db* and *ob* mice and revolutionized our view of adipose tissue, not only as a hormonally regulated fat depot, but also as a lipostatic endocrine organ and the source of leptin. Due to the discovery that *db* is a mutation of the leptin receptor gene and *ob* is a mutation of the leptin synthesis gene, the nomenclature of these two mice species has been changed to *lepr^{db}* and *lep^{ob}*, respectively. Unfortunately, the early hope that exogenous peripheral injection of leptin would treat obesity in humans has not materialized. However, administration of leptin was highly effective in the rare morbidly obese patients with mutations of the leptin gene that produces an ineffective leptin protein (see Chap. 10). These data suggest an important hitherto unknown role for leptin in human body weight regulation. However, it should be taken into consideration that the mode of action

of leptin in mice may not be fully applicable to humans, as discussed by Himms-Hagen.¹⁴⁹

Leiter¹⁵⁰ proposed to differentiate between the consequences of gene expression and the diabetes susceptibility-conferring effects of the Ks background using the response to estrone. The estrone-treated mice were hyperphagic and obese, but they did not develop hyperglycemia or islet atrophy. He postulated that the estrone:androgen ratio is critical to glucose homeostasis. In *db/db* mice, this ratio could be regulated by the activity of sulfotransferases, liver enzymes that render steroids receptor-inactive by conjugation with sulfate. At puberty, the sulfotransferases sulfate estrogens but not androgens, thus inducing diabetes. Estrone supplementation is protective, because estrogens appear to prevent the interaction with diabetogenic background modifiers. The hepatic sulfation capacity might then potentiate the diabetogenicity of the *db* mutation,¹⁵¹ and the development of a diabetic phenotype depends on the strength of interaction between the *db* gene and sulfotransferases. The number of hepatic insulin receptors was reduced in estrone-treated mutants, indicating that this was not a secondary insulin-elicited downregulation. There was no difference in the sensitivity of β cells to glucose. Thus *db* expression appears to be associated with a membrane defect causing scarcity of insulin receptors, independent of obesity and insulinemia.

In addition, the genomic factors inherent in the BLKs background of *db/db* mice facilitate the lesion of β cells. Their influence is harmful by limiting their replication and adversely sensitizing them to hyperglycemia. This is demonstrated by the observation that the growth of islets genetically implanted in the spleens of nondiabetic BL/6J mice far exceeds that of islets implanted in the spleens of nondiabetic BLKs mice.^{152,153}

INSULIN-RESISTANT MUTANT RODENTS WITH SUSTAINED INSULIN SECRETION

ob/ob Mice Now Relabeled as *lep^{ob}*

In contradistinction to *db/db* mice, which lose their β cells in the course of insulin-resistant diabetes, the C57BL/6J-*ob/ob* mice, also originating from the Bar Harbor Jackson Laboratory,^{134,135} have been investigated mainly due to their remarkable obesity, reaching up to 90 g body weight. The aspects of hyperinsulinemia and hyperglycemia are mainly discussed here. The autosomal recessive, fully penetrant *ob* mutation is located on chromosome 6 (see Chaps. 10 and 23 for a fuller discussion of obesity).

ob/ob Mice are characterized by hyperphagia, insulin resistance, hyperglycemia, remarkable obesity, and sustained insulin secretion. β -Cell hyperfunction leading to 10- to 50-fold higher than normal hyperinsulinemia persists during their life span, and compensates in large part for resistance, limits the overactive gluconeogenesis to moderate hyperglycemia, and prevents ketosis by promoting lipogenesis despite an increased FFA turnover. Paradoxically, lipogenic enzymes are also highly active, concurrently with those of gluconeogenesis. The close interrelation of obesity and diabetes in this syndrome has led to the definition of this condition as *diabesity*.⁵

Pancreatic insulin content is very high, the highest of any mice mutant with diabesity. In contrast to the *db/db* cells, they exhibit a very pronounced hypertrophy/hyperplasia and a reduced population of α , δ , and PP cells. Islet area doubles by the age of 1 month and increases 30-fold by 6 months.¹⁵³ Any degranulation caused by profuse insulin release is offset by regrowth in other islets.

This robust insulin secretion reduces the hyperglycemia by attenuating the hepatic gluconeogenesis on one hand, and pushing glucose carbons into fat synthesis on the other hand. The enhanced lipogenesis leading to obesity actually has an antihyperglycemic effect. By converting the glucose surplus to lipid in the liver and adipose tissue, the hyperglycemia in *ob/ob* mice is moderate. Insulin resistance in *ob/ob* mice, as in other "diabese" animals, appears to be due to diminished insulin binding to receptors, impaired autophosphorylation, and reduced signal transduction.⁵⁸

The genetic defect in *ob/ob* mice is the lack of satiety-controlling factors, as elegantly demonstrated by the parabiosis experiments (see *db/db* mice, above) and confirmed by the discovery that leptin action is missing in *ob/ob* mice by virtue of a mutation in the leptin gene. The role of the associated hypothalamic peptides in neuroendocrine glucoregulation has been recently reviewed.¹⁵⁴⁻¹⁵⁶ Levels of neuropeptide Y (NPY), a potent insulin-suppressible appetite stimulant, are high in diabese animals, possibly as a result of leptin deficiency.

Yellow Obese Mice

The mutation in yellow obese mice was established as an allele at the agouti locus of chromosome 2. It was assigned the gene symbol A^y for yellow, because the yellow skin pigmentation and obesity are interconnected in this dominantly inherited mutation. Homozygosity is lethal and all the obese offspring are heterozygous for the A^y gene. Another dominant allele at the agouti locus, labeled A^{vy} for viable yellow, arose spontaneously in C3H/HeJ mice at Bar Harbor. Both adiposity and hyperinsulinemia are related to the degree of yellow in the pigmentation.

Two reviews^{157,158} supply information on the yellow diabese mice and their response to various pharmacologic interventions. Blood glucose levels are higher in the obese than in nonobese individuals only in the fed state, indicating IGT rather than overt diabetes, but their responses to cortisone are exaggerated. Hypertrophy and hyperplasia of islets appear, especially on a carbohydrate-rich diet, leading to hyperinsulinemia prior to weight gain. Hyperphagia and obesity in the young are more pronounced in males than in females. Fat tissue lipogenesis is enhanced even on fasting. Longevity depends on body weight and fat content of the diet. The adrenal glands of yellow obese mice are enlarged and adrenalectomy prevents islet β -cell hypertrophy and insulin resistance. This may be mediated by the attenuation of hyperphagia that is induced by glucocorticoids, as in other animals with the diabesity syndrome. The underlying abnormality is due to faulty expression of the agouti gene in the hypothalamus, in addition to the hair follicle, due to aberrant splicing of the agouti mRNA coding region.¹⁵⁸

KK Mice

The history, metabolic-endocrine features, and pharmacologic utility of KK mice have been reviewed by Taketomi and Ikeda,¹⁵⁹ who also listed the trials of antidiabetic modalities in these mice. The KK strains and hybrids differ with respect to the degree of obesity and glucose homeostasis, but obesity seems to be the primary factor precipitating the insulin resistance.

The KK hybrids and the yellow KK mice develop overt diabetes along with weight gain on a regular diet, whereas the Japa-

nese KK mice require a high-energy diet for the diabetes to become expressed. The KK inheritance was suggested to be dominant with 25% penetrance, due to the association with a recessive modifier, but evidence for polygenic inheritance was also provided. Quantitative trait loci analysis was performed by Suto and associates.¹⁶⁰ Nonfasting hyperglycemia is <300 mg/dL (17 mmol/L), and weight reaches a peak of 50 g at 5 months and is more marked in males than females. Nonfasting hyperinsulinemia may reach levels up to 1200 μ U/mL. IGT is also more marked in males than in females and improves with age. KK mice have high plasma glucagon levels and deficient suppression of glucagon release by glucose. Treatment with growth hormone or glucagon worsens the hyperglycemia.

The hyperglycemia in all KK strains is associated with high levels of activity of glycolytic and lipogenic enzymes, concordant with the degree of hyperinsulinemia. However, the activity of gluconeogenic enzymes also rises, in spite of hyperinsulinemia. These findings emphasize the failure of insulin to suppress gluconeogenesis, while stimulating glycolysis and lipogenesis, similarly to the metabolic derangements in *db/db* mice. Insulin resistance in KK mice is due to changes in the expression of signal transduction components, among them IRS-1 and phosphatidylinositol-3-kinase (PI-3-kinase).¹⁶¹

A prominent feature of the KK mice is β -cell hyperplasia and elevated insulin content, as well as an expanded endoplasmic reticulum, Golgi apparatus, and possible transformation of ductal cells into β cells. Partial β -cell degranulation occurs at high glucose levels, but there is no evidence of necrosis. Like other diabese rodents, yellow KK mice exhibit high corticosterone levels and adrenal hyperplasia. However, obesity, glycemia, and insulinemia precede the adrenal changes, indicating that they are probably secondary rather than causal. Hyperphagia is a common finding in all KK strains, but its onset is not as early as in other diabese mutants. Hyperglycemia, hyperinsulinemia, obesity, the response of hepatic gluconeogenesis to insulin, and sensitivity to exogenous insulin all tend to revert to normal at 1 year of age. Nevertheless, the life span of diabetic KK mice is significantly shorter.

New Zealand Obese (NZO) Mice

The polygenic New Zealand obese (NZO) strain was developed from a mixed colony of mice by selective breeding for heavy weight, until obesity with mild hyperglycemia and hyperinsulinemia became established. Body weight rises rapidly during the first 2 months of life, conforming to the hyperphagia. Later on, weight gain is sluggish, up to a peak of about 90 g at 12–14 months, as in other strains of obese mice. Peak glycemia of $\sim$ 250 mg/dL (14 mmol/L) occurs at 4–6 months and is more pronounced in males than females. Gluconeogenesis in the liver is increased despite hyperinsulinemia. The features of the NZO diabetes have been reviewed in detail.^{162,163}

Hyperfunction of β cells is evident from high insulin secretion, when compared with either Swiss or BL/6 mice as reference, since genetic controls are not available. There is a wide spectrum of plasma insulin values and secretory responses in NZO mice, perhaps due to differences in randomly bred NZO colonies. However, there is definite hyperinsulinemia, though it is less marked than in *ob/ob* or KK mice. Pancreas insulin content is 2–4 times higher in 3-month-old mice and 6–10 times higher in 8-month-old mice. Insulin levels and obesity decline with age.

The insulin secretion pattern in NZO mice is abnormal.¹⁶⁴ The plasma insulin level in fasted mice is similar to that of fed mice and 2–3 times higher than in controls. The islet responses to tolbutamide, cyclic AMP, or glucose are low, and the effects of glucagon or aminophylline are delayed. The calcium ionophore isobutylmethylxanthine (IBMX) promotes insulin release from islets of fasted mice but does not augment the effect of glucose. Arginine elicits a good response. The refractoriness to glucose may be related to limited islet glucose metabolism in relation to insulin output, with an impediment prior to the triose phosphate step, as glyceraldehyde provokes a potent insulin release. A common denominator in these patterns of insulin secretion is a blunted first phase of release. A single injection of a cyclic AMP elevating “islet activating protein” lowered the blood glucose level for as long as 5 days and improved the secretion of insulin in response to glucose *in vivo* and in isolated islets.

Insulin resistance is remarkable. Large doses of exogenous insulin hardly affect the blood glucose level but intraperitoneally implanted islets from albino mouse donors reverse the hyperglycemia. *In vitro* glucose uptake by muscles is low. Basal and insulin-stimulated 2-deoxyglucose transport is reduced as is glycogen in muscles in young mice.¹⁶⁵ Adipose tissue was also found to be insulin resistant, as evidenced by a defect in insulin-mediated stimulation of the activity of pyruvate dehydrogenase.¹⁶⁶ The activity of glycolytic enzymes, glucokinase, and pyruvate kinase is elevated, and the activity of the gluconeogenic PEPCK and glucose-6-phosphatase is reduced, as would be expected in a hyperinsulinemic state, in contrast to other diabese animals. However, the activity of fructose-1,6-bisphosphatase is not reduced by the hyperinsulinemia, despite high levels of its specific intracellular inhibitor, fructose-2,6-phosphate. It was suggested that the abnormal regulation of this enzyme contributes to the increased hepatic glucose production.^{167,168}

Lipogenesis is increased both in the liver and adipose tissue. NZO mice are susceptible to the amount and composition of food, and adipose tissue responds to a fat-rich diet with hypercellularity. The ratio of total to peritoneal adipose tissue is 2.5 in the NZO and 3.5 in the *ob/ob* mice.¹⁶⁹ In NZO mice (as in humans), the peritoneal fat predominance may accentuate the metabolic disturbances.

Of concern is the detection of humoral antibodies to insulin receptors, and possibly also to islets, in NZO mice, suggesting that the tissue insulin resistance may be at least in part of immune origin. However, β -cell autoimmunity in a hyperinsulinemic animal is highly unlikely, and there is no evidence for a β -cell destructive process. The New Zealand strains of mice have, in general, a high incidence of other autoimmune disorders, such as glomerular nephritis with deposition of immune complexes. Therefore, an interaction between general autoimmunity and some aspect of diabetes of NZO mice cannot be completely ruled out.

fa/fa (Zucker) Rats Now Labeled *lepr^{fa}*

The *fa* gene is a spontaneous autosomal recessive mutation on rat chromosome 5. On the basis of the flanking genetic markers, the *fa* gene is now considered to be the rat homologue of the mouse mutant *db* gene,¹⁷⁰ located on chromosome 4, which has now been shown to produce a mutated leptin receptor.

The pathophysiology of the *fa* mutation has been extensively reviewed.^{171,172} Homozygous *fa/fa* rats develop hyperphagia and

extreme obesity, recognizable at 1 month of age by the prominent growth of subcutaneous and intraperitoneal fat depots. This is accompanied by mild hyperglycemia, IGT, marked insulin resistance, and hyperinsulinemia. Phenotypically, the *falfa* rats appear similar to *ob/ob* mice. They exhibit early and persistent hyperphagia, long-lasting hyperinsulinemia, and obesity without ketosis. However, there are differences in the extent of hyperglycemia in relation to hyperinsulinemia and insulin resistance, and there is a pronounced hyperlipidemia in *falfa* rats. No genomic modifiers have been demonstrated, and the nature of primary defect(s) causing the hyperphagia and hyperinsulinemia also appears to differ from those of the obese mice.

Islets of *falfa* rats exhibit both hypertrophy and hyperplasia with pronounced microtubule formation, which is sustained throughout most of their life without β -cell exhaustion, despite lasting overstimulation. In these respects *falfa* rats resemble *ob/ob* mice. The *falfa* rats oversecrete insulin even when fed a diet identical in carbohydrate content to their lean controls. Support for an intrinsic defect causing oversecretion comes from the observation that insulin release from isolated islets is not normalized after culturing for as long as 21 days, and that islets cultured at low glucose concentrations exhibit an exaggerated glucose-stimulated response that is not inhibited by mannoheptulose.¹⁷³ The dissociation between hyperphagia and hyperinsulinemia is apparent in long-term experiments. Food restriction throughout life does not preclude the development of hyperinsulinemia, obesity, and the induction of insulin-dependent enzyme systems of hepatic lipogenesis and adipose tissue triglyceride uptake.

The females are sterile and males have also fertility problems, which may be alleviated by adrenalectomy. Lean, heterozygous *fa/+* rats are employed for breeding a progeny with a 25% incidence of obesity, or *falfa* males are treated with testosterone. The role of glucocorticoids was discussed in depth by York,¹⁷⁴ stressing that these hormones are required for the development of diabetes in *falfa* rats and other mutants by acting both at peripheral and central sites. The diabetes is characterized by increased availability of glucocorticoids from the enlarged adrenal glands. The hyperinsulinemia appears to be caused by CNS signals transmitted to the pancreas via the vagus nerve.¹⁷⁵ Further evidence for the anomalous performance of the hypothalamo-pituitary axis is the dysregulation of NPY mRNA and corticotropin-releasing factor (CRF). Abnormal cerebral glucose utilization has been found by Rohner-Jeanraud and colleagues.^{176,177} Tissue unresponsiveness to insulin is ameliorated by adrenalectomy, which also lowers food intake, decreases the efficiency of energy use, and depresses lipogenesis.¹⁷⁸

Insulin resistance is prominent in *falfa* rats. A comparison with ventromedial hypothalamus (VMH)-lesioned rats reveals greater tissue insulin resistance in *falfa* rats under similar insulin and obesity conditions. Insulin resistance is evident in perfused hindlimb muscle, both with respect to glucose transport and lactate oxidation. However, insulin sensitivity in the heart appears normal, although actual glucose transport and metabolism may be decreased. In a euglycemic insulin clamp study, total glucose use in obese rats was achieved only at 3.5-fold higher insulin concentration, similar to that of lean rats.¹⁷⁹ Muscle insulin resistance was not suggested to be the primary etiologic cause of diabetes, on the basis of 2-deoxyglucose uptake studies in young animals.¹⁸⁰ However, there is a substantial decrease in IRS-1 protein, insulin-stimulated IRS-1 phosphorylation, and the expression of PI-3-kinase,¹⁸¹ consistent

with deficient GLUT-4 translocation,^{182,183} which seems to provide the molecular basis for muscle insulin resistance in *falfa* diabetes. Oxidative stress has also been implicated in the attenuated glucose transport in skeletal muscle.¹⁸⁴ Hepatic VLDL secretion is increased, giving rise to a marked VLDL hyperlipidemia.¹⁸⁵ The activity of the receptor TK, lipogenic enzymes, and lipoprotein lipase (LPL) was found to be increased in adipose tissue of *falfa* rats.¹⁸⁶⁻¹⁸⁸

The secretion of amylase by the exocrine pancreas is also disturbed. Amylase synthesis is insulin dependent and its activity is reduced in insulinopenic conditions. Interestingly, amylase synthesis was found to be reduced in the hyperinsulinemic, but insulin-resistant *falfa* rats and *ob/ob* mice.¹⁸⁹ These observations indicate that insulin resistance is also manifest in proximal acinar cells, preventing the expression of the amylase gene.

In young *falfa* rats, adipose tissues grow by hyperplasia and hypertrophy up to week 14, whereas in the older obese rats, adipocyte proliferation continues until at least week 26, in association with striking cell hypertrophy. Early nutritional abundance has a pronounced impact on adipose tissue development, the cellularity increasing in both *falfa* and lean rats, while restricted feeding reduces the adipocyte number in lean rats only. Adipose tissue has an increased capacity to take up preformed fat through the insulin-induced LPL. *falfa* Rats, compared with normal rats on long-term insulin infusion, had both increased LPL expression and activity, but LPL mRNA was elevated only in the former.

BBZ Rats

Female *falfa* rats have been crossed with the autoimmune male BB rats and named BBZ/Wor. As described by Guberski and coworkers,^{190,191} when heterozygous *falfa* females were mated with diabetic BB/Wor males, the first generation was nondiabetic and lean. When the F₁ females were then backcrossed to BB/Wor diabetic males, 18% of the offspring developed diabetes but remained lean. The third mating was an intercross between the backcross diabetic males and females, of which 74% became diabetic. The fourth cross was between the third-cross progeny and F₁ animals, enabling the selection of carriers of both diabetes and *fa* genes. Of the resultant two groups of lean and obese progeny, about 25% were obese and about half of them became diabetic at around 3 months of age, with a mean blood glucose level near 400 mg/dL (22 mmol/L). Also, slightly more than half of the lean group developed diabetes at around 3 months with a similar blood glucose level.

The BBZ/Wor rat shows surprising differences between the lean and obese offspring. Lean BBZ rats exhibit insulinitis with β -cell loss, ketosis, weight loss, and a requirement for exogenous insulin, similarly to the original BB rats. Obese BBZ rats show prominent islet hyperplasia coincident with insulinitis and degranulation, are often hyperglycemic but maintain their weight, rarely experience ketosis, and survive without insulin treatment. Apparently the β -cell destructive process is counterbalanced by islet regeneration. Thus the BBZ/Wor rat presents a mixed type 1/type 2 diabetes syndrome, comprising features of both autoimmunity and insulin resistance. They develop hypertension and hyperlipidemia,¹⁹² retinopathy, and neuropathy,¹⁹³ and represent a relevant model for exploring the condition of β -cell destruction compensated by β -cell proliferation.

The Diabetic *fa/fa* Rat: ZDF/Drt-*fa*

A substrain of *fa/fa* rats, selectively inbred for hyperglycemia,¹⁹⁴ is useful for the investigation of T2DM. Nonfasting plasma glucose levels exceed 400 mg/dL (22 mmol/L) at 10 weeks of age in males. The hyperlipoproteinemia is similar to that seen in the regular *fa/fa* rats, but the weight gain and insulin levels are lower. These rats also acquire neuropathy and other complications not exhibited in *fa/fa* rats. ZDF/Drt-*fa* rats have a reduced expression of muscle GLUT-4 transporter, most probably as a result of hyperglycemia.¹⁹⁵ In contrast to *fa/fa* rats, the capacity to oversecrete insulin is limited, and they manifest labile, glucose-sensitive β cells that proceed to apoptosis.¹⁹⁶ They also demonstrate downregulation of β -cell GLUT-2 transporters,¹⁹⁷ which may impair insulin synthesis, thus inducing severe type 2-like diabetes. Food restriction in the prediabetic stage in ZDF rats may prevent β -cell deterioration and loss of GLUT-2.¹⁹⁸ A deleterious lipotoxic effect of high plasma FFA and β -cell triglyceride levels on β -cell function has been suggested by Unger and collaborators.^{199–201}

Obese-Hyperglycemic Wistar Kyoto Fatty Rat Group

As reviewed by Kava and colleagues²⁰² and Odaka and associates,²⁰³ this group of rats with polygenic diabetes-hypertension was derived from reciprocal crosses between the *fa/fa* and the glucose-intolerant Wistar Kyoto (WKY) rats in Japan. The original strain, obtained after several crosses and inbreeding, shows both peripheral and hepatic insulin resistance and hyperinsulinemia. Males are hyperglycemic and females become hyperglycemic only on a sucrose-rich regimen. Several variants were developed and referred to as WDF/Ta-*fa* rats,²⁰⁴ or Wistar diabetic rats, and WKY/N Drt-*fa*,²⁰⁵ also known as WKY fatty rats.

The outbred males of the WDF/Ta-*fa* substrain exhibit hyperglycemia on a high-sucrose diet; females do not develop hyperglycemia, but both genders are hyperinsulinemic. Castration does not abolish the sexual dimorphism, whereas it does improve insulin sensitivity in *fa/fa* rats. Neonatal ovariectomy did not aggravate the diabetes, indicating no estrogen protection. Males are more hyperphagic than females, which could account in part for the sex difference. High hepatic glucose production with elevated PEPCK activity that was abolished by adrenalectomy was demonstrated. Hypertrophic islets were prominent with pronounced insulin content secretion, but this did not compensate for the hyperglycemia. Insulin resistance in males was associated with downregulation of muscle insulin receptors, leading to decreased insulin binding. TK activity per receptor was also reduced, as compared with *fa/fa* rats, again demonstrating the detrimental effect of hyperinsulinemia on receptor function.⁵⁸

The WKY fatty rats in Japan were reported to be spontaneously hypertensive and nephropathic.²⁰⁵ Insulin resistance was attributed to enhanced muscle TNF α production, inducing an impairment of postreceptor insulin signaling. The WKY diabetic strain was also raised in the United States by crossing with the WKY/N stock.²⁰⁴ The colony suffered from infections and had to be maintained in specific-pathogen-free (SPF) condition. The animals delivered by cesarean section were more diabetic than those pre-cesarean derived. It is interesting that the infections reduced the incidence of type 2-like diabetes in these animals, analogously to the effect of pathogens on the diabetes in BB rats and NOD

mice, even though the WKY fatty rats were without autoimmune background.

Diabetic Corpulent Rat Group

Rats with type 2-like diabetes and hypertension were developed from two congenic strains, SHR/N and LA/N, at the NIH in Bethesda, Maryland (substrain code N). The SHR/N-*cp* and the LA/N-*cp* rats were obtained by introducing into these backgrounds the *cp* gene of the Koletzky SHR strain, which carries one *fa* allele. The investigators preferred the name “corpulent” and symbol *cp^{fa}* or *fa^{cp}*, but the new proposed designation is *lepr^{fa/cp}*. Details on the backcrosses that led to the different substrains have been provided by Greenhouse and associates.²⁰⁶ The important feature of the *cp* gene is that a small difference in the genomic background leads to substrains that markedly differ in the degree of hyperglycemia, hyperlipidemia, insulin resistance, hypertension, nephropathy, atherosclerosis, and propensity to myocardial lesions.²⁰⁷ These leptin receptor–abnormal rats are infertile, which requires test mating each generation to identify the individuals for the next cross with the partner strain. Mating the congenic heterozygotes yields a lean to corpulent ratio of 3:1 at 5 weeks of age.

SHR/N-*cp* Rats

SHR/N-*cp* males are moderately hypertensive; manifest hyperlipidemia, hyperinsulinemia, glucosuria, and proteinuria; and become hyperglycemic on a sucrose-rich diet.²⁰⁸ They show marked and long-lasting β -cell hyperplasia. Insulin receptor malfunction is suggested by decreased insulin binding by liver membranes and by enhanced gluconeogenesis. Muscle GLUT-4 is reduced ~40% in SHR/N-*cp* rats compared with lean controls, whereas the insulin-independent GLUT-1 is increased by ~40%.²⁰⁹ Corpulence is due to both adipocyte hypertrophy and hyperplasia and pronounced hepatic lipogenesis. Serum concentrations of counterregulatory hormones, glucagon, corticosterone, growth hormone, and somatostatin are elevated. Corpulence and insulin resistance subside after 1 year. SHR/N-*cp* females are smaller and less glucosuric, and rarely exhibit nonfasting hyperglycemia.

Long-term sucrose feeding of SHR/N-*cp* males results in weight gain and accentuates the hyperglycemia, hyperinsulinemia, IGT, and pancreatic islet hyperplasia. SHR/N-*cp* rats are prone to glomerulopathy, which is aggravated by the sucrose diet, as are the hypertension and proteinuria.²¹⁰ Renal changes are consistent both with diabetic nephropathy and inflammation, showing segmental, diffuse, and nodular intercapillary mesangial expansion, which may be an outcome of hyperglycemia and concomitant hypertension.

SHHF/Mcc-*cp* Rats

The SHHF/Mcc-*cp* rats maintained by McCune and colleagues²¹¹ evolved on a genomic background conducive to the expression of cardiomyopathy, dramatically presenting as congestive heart failure (CHF). The CHF is expressed in 100% of animals in association with hypertension and diabetes. Renal changes similar to those in the SHR/N-*cp* strain also occur, particularly in females. The mode of inheritance is polygenic, but the presence of the *cp^{fa}* gene is essential. Sexual dimorphism is seen in the onset of CHF expression, as is the diabetes and hyperlipidemia, which includes also heterozygote littermates. Early death occurs in the following

order: males, females, lean males, and lean females. Clinical symptoms resemble those of human CHF: pronounced cardiomegaly, edema, hydrothorax, ascites, dyspnea, and visceral hyperemia, as well as a pattern of changes in atrial natriuretic factor, norepinephrine, aldosterone, and renin. Morphologic observations indicate degeneration of myocytes. Estrone treatment delays but does not prevent CHF. The calcium channel blocker nifedipine reduces body weight, cardiac hypertrophy, and blood pressure, and improves glucose homeostasis, mainly in females.²¹²

JCR:LA-*cp* Corpulent Rats

Backcrosses of LA/N-*cp* males with a hooded rat species produced an outbred substrain JCR:LA-*cp* with only about 3% contribution of the SHR gene but the presence of the *fa* allele. As reported by Russell,²¹³ these rats are not hypertensive, but hyperinsulinemic and insulin resistant, with pronounced hyperlipidemia, diabetes, and hepatic lipogenesis.²¹⁴ Their prominent feature is early cardiovascular disease (CVD) with atherosclerotic lesions of major blood vessels. Such lesions do not appear in *fafa* or SHR/N-*cp* rats. The lesions were morphologically classified into stages, assumed to represent the progression and repair of the ischemic damage, ranging from inflammatory cell infiltration through myocytolysis to advanced focal infiltration with scavenging and collagen bands, with scars at various stages of maturity.

JCR:LA-*cp* males show a greater incidence of CVD than females, approaching 100% at the age of 9 months. The appearance of occlusive thrombi in coronary arteries indicates that the nature of the lesion is ischemic-atherosclerotic, although not related to plasma cholesterol concentration. Food restriction, strenuous exercise, alcohol intake, or suppression of lipogenesis by a dicarboxylic acid compound (MEDICA 16)²¹⁵ delayed the incidence and progression of CVD in association with a decrease in insulin resistance. Castration reduced hypertriglyceridemia, but was without effect on the vascular lesions, indicating that estrogens were not protective. Conversely, nifedipine prevented the formation of advanced lesions without improving insulin resistance. On the other hand, assuming that the hyperinsulinemia is responsible for the frequency and severity of CVD, it was proposed that the susceptibility to CVD is due to hyperinsulinemic stress, which initiates the primary endothelial injury, which in the face of hyperlipidemia, excessive caloric intake, and genetic factors progresses to intimal atheroma and reduces the life span of JCR:LA-*cp* rats.^{216,217}

RODENTS WITH SPONTANEOUS DIABETES OF VARYING ETIOLOGY

Nonobese Nondiabetic (NON) Mice

NON mice were bred in Japan from the same CTS line from which the NOD mice were derived, but they do not manifest β -cell targeted autoimmunity. The haplotype of NON mice, H-2^b, is distinct from the H-2^k of the NOD mice. The derivation, genetics, diabetic features, and complications have been described by various authors in recent reviews.^{101,218,219} Male NON mice display IGT at 9 weeks of age. The insulin content and the insulin-mRNA content in the pancreas are low, about one-third that of control ICR mice. The first-phase insulin response is absent in the perfused NON mouse pancreas, and the insulin:glucose ratio after IV glucose injection is low. Insulin-binding studies in muscle do not suggest insulin resistance. However, NON mice show a tendency to obesity on hyper-

caloric diet, islet hyperplasia, and insulin hypersecretion after a hypothalamic gold thioglucose lesion. Thus the NON mice represent a hypoinsulinemic animal, with an "intrinsic" β -cell defect in insulin secretion and synthesis, but retaining the potential for β -cell proliferation when triggered by hyperphagia or hypothalamic stimulation. NON mice are prone to nephropathy, even in the face of only mild hyperglycemia, exhibiting glomerular lesions with lipid deposition and lymphocytic infiltration.

WBN/Kob Rats

WBN/Kob rats have been raised from Wistar specimens originating in Basel, Switzerland, and investigated in Japan by Mori and coworkers.^{220,221} Diabetes occurs spontaneously in 40% of males at 9 months and in 90% at 12 months of age. The striking feature of this genetically recessive syndrome is a lesion in both exocrine and endocrine pancreas, involving β and α cells and acini, with decreased insulin, glucagon, and amylase content. The onset of hyperglycemia and glucosuria is gradual and accompanied by weight loss rather than obesity, and is accelerated on a high-energy diet. The animals are not insulin resistant and respond well to exogenous insulin. The insulinopenia is associated with a decrease in the number and size of islets and multifocal fibrosis extending to the exocrine pancreas. An infiltration of the pancreas with inflammatory cells is noted, as well as fibrous exudation around the pancreatic ducts and capillaries, with deposition of hemosiderin by 3 months of age. These changes suggest a slow autoimmune process; however, the morphologic findings are distinct from those of NOD mice and BB rats. Ocular, renal, and neural lesions typical of diabetes have been reported.²²²

eSS Rats

The eSS rats, bred in Argentina, are characterized by a slow onset of IGT and hyperglycemia, more severe in males, which becomes conspicuous at about 1 year of age. The colony development, prolonged inbreeding, and the polygenic inheritance pattern together with metabolic-endocrine and morphologic features have been reviewed in detail.²²³ Islets of 6-month-old eSS rats show an interstitial tissue growth, vacuolization, and a disrupted pattern due to separation by fibrous deposits with a compensatory hyperplasia (resembling nesidioblastosis). eSS rats are somewhat overweight, insulin resistant, hyperinsulinemic, and hyperlipidemic. Food restriction slows down the progression to diabetes, whereas a high-energy diet accelerates the onset of metabolic abnormalities and chronic complications in kidneys, nerves, and lenses and shortens the life span of the animals. Aggravation of diabetic symptoms was noted on a high-sucrose diet.²²⁴

BHE/Cdb Rats

As related by Berdanier,²²⁵ the BHE/Cdb rat strain was developed as a model of type 2 nonobese diabetes, by crossing Osborne-Mendel rats with a Pennsylvania State College strain. Cdb rats, compared with Wistar rats, have a shorter life span, fatty livers, and nephropathy. Females are more susceptible to these changes, whereas males exhibit a moderate hyperglycemia and mild hyperlipidemia prior to insulin elevation. The abnormalities seem to start at the insulin target tissues rather than at the β -cell secretion level; however, at 150 days the pancreatic insulin stores are decreased. As hepatic lipogenesis is enhanced prior to alterations in glucose

homeostasis, defects in hepatic metabolism seem to characterize the phenotype. Slow mitochondrial respiratory rates that deteriorate with age were demonstrated, with enhanced lipogenesis linked to lower mitochondrial oxidation. A mutation in the mitochondrial ATPase gene related to the IGT was reported.²²⁶

OETF Rats

Male OETF rats manifest a spontaneous IGT, hyperglycemia, and moderate hyperinsulinemia at about 18 weeks of age and are overweight. This mutation was discovered in the Otsuka Long Evans Tokushima colony of rats, from which the LETL rats with autoimmunity also originated, and was reviewed recently by Kawano and associates.^{227,228} β -Cell infiltration with fibrotic tissue and mononuclear cells is seen around the time of onset, followed by β -cell enlargement due to intraislet fibrotic tissue and hemosiderin deposits. Deposition of fat droplets as a consequence of hypertriglyceridemia was also present.

The OETF rats develop a pronounced nephropathy, with clinical and pathological features resembling human diabetic nephropathy, characterized by marked thickening and rupture of the glomerular basement membrane, focal mesangial lesion, fibrin cap, and aneurysmal dilatations of intraglomerular vessels.

NSY Mice

The Nagoya Shibata Yasuda mice were selectively inbred for glucose intolerance from JcI:JCR mice. They represent a model of T2DM, but are not severely obese, with a cumulative incidence of diabetes of 98% in males and 31% in females. A polygenic inheritance pattern affecting insulin secretion and insulin sensitivity was mapped on four loci on chromosomes 6, 11, and 14. The NSY mouse may serve as a model for studies of the etiology of late onset of T2DM.²²⁹

Koletzky (SHROB) Rats, Now Labeled *fa^K*

The SHROB rat exhibits obesity, marked hyperinsulinemia, severe insulin resistance, hypertriglyceridemia, nephropathy, and hypertension.²³⁰ The obese phenotype results from a mutation in the leptin receptor²³¹ designated *fa^K* that resides on the same allele as the *falfa* rat. Although the SHROB rats have IGT and corticosteronemia, they are normoglycemic in the fasting condition. Because of this property, they may represent a model for investigation of gene modifiers that dissociate obesity from hyperglycemia. The insulin receptor and its IRS-1 substrate are underexpressed. Increased activity of the sympathetic nervous system was proposed to be responsible, by separate pathways, for both hypertension and insulin resistance.

RODENTS WITH OVERNUTRITION-EVOKED INSULIN RESISTANCE AND DIABESITY

Psammomys obesus (Sand Rat)

Although often called sand rats, these animals are gerbils, and their popular nickname stems from the fact that they were trapped on the

sandy shores of the Nile Delta. They subsist on a diet of succulent halophilic plants and have no evidence of diabetes in their North African or eastern Mediterranean habitat. Hyperinsulinemia, hyperglycemia, and obesity develop on transfer to *ad libitum* rodent laboratory chow. The history and features of the nutritionally induced diabetes in *Psammomys* have been updated,^{232–235} and these reviews should be consulted for details.

Pronounced insulin resistance is evident on a high-energy (HE) diet relative to their native regimen. In the Jerusalem colony, derived from the Dead Sea region, the progression to diabetes was classified into four stages, according to serum insulin and glucose levels.²³⁶ Stage A comprises normoglycemic and normoinsulinemic animals. In stage B the animals gain weight and remain normoglycemic, but become markedly hyperinsulinemic, which compensates for the insulin resistance. In stage C the *Psammomys* animals become hyperglycemic despite extreme hyperinsulinemia. They show a pronounced peripheral insulin resistance, manifested by reduced muscle uptake of 2-deoxyglucose and diminished GLUT-4 protein and mRNA.^{235,236} The hepatic resistance is expressed as excessive gluconeogenesis due to nonsuppression of PEPCK; however, the hepatic lipogenesis remains responsive to insulin, with prominent adipose tissue lipid uptake and concomitant obesity. The effectiveness of the augmented insulin secretion is low, as a substantial proportion is secreted as proinsulin and its intermediate conversion products.²³⁷ In stage D, the plasma insulin levels drop and adipose tissue weight decreases, signifying a decline in insulin secretion. Animals at this stage show massive depletion of β -cell insulin granules²³⁸ and apoptosis^{152,239} and develop ketoacidosis. They then require exogenous insulin for survival. Longitudinal follow-up²⁴⁰ demonstrates a characteristic bell-shaped curve (Fig. 16-3). Similar progression to full-fledged diabetes was seen in another colony of *Psammomys* from Algeria that was maintained in France,²⁴¹ and in a branch of the Israeli

FIGURE 16-3. Scattergram illustrating the bell-shaped pattern of progression of *Psammomys obesus* to diabetes on a high-energy diet. Stage A: Normoglycemia and normoinsulinemia. Stage B: Hyperinsulinemia and normoglycemia. Stage C: Hyperinsulinemia and hyperglycemia. Stage D: Insulin depletion with marked hyperglycemia. Note the clustering of animals in stage B. Longitudinal studies on a group of 37 *Psammomys* for 16 weeks after weaning. The data are from animals that are a branch of the Jerusalem colony maintained at Deakin University in Australia. (Adapted from Howard.²⁷⁰)

colony maintained in Australia.^{242,243} In the latter colony the nutritional obesity and insulin resistance were found to be associated with hyperleptinemia and resistance to exogenous leptin.²⁴⁴

The progression of *Psammomys* to diabetes resembles that of *db/db* mice, with an important difference: β -cell loss in *Psammomys* is not solely determined by genetic mutation or by a background genome because the *Psammomys* reverts from stage C or B to A on food restriction alone. Some *Psammomys* were found to remain in stage A even on the HE diet, which led to the isolation of a diabetes-resistant line.²⁴⁵ The diabetes-prone animals progress on the HE diet to stages C or D within 2–3 weeks, whereas the diabetes-resistant animals stay normoglycemic.

Psammomys represent a model for the β cell loss resulting from massive, continuous insulin resistance imposing compensatory β cell oversecretion. This is evident from fading immunostaining of insulin, of GLUT2 transporter in the plasma membrane and of glucokinase in the cytoplasm of β cells.²⁴⁶ These changes become apparent only in Stage C with the development of hyperglycemia, with shrinking of β cell volume and content. This is significantly correlated with the level of glycemia. Thus, the increasing glycemia is most likely responsible for the loss of β cell secretory capacity and apoptosis.

Insulin binding by hepatic and muscle insulin receptors is low in stage A *Psammomys*, about one-fifth that in the albino rat, indicating a low receptor density.²⁴⁷ The activation of TK by insulin on isolated insulin receptors from liver or skeletal muscle at stage A is similar to that of the albino rat per receptor, but it becomes impaired in stages B and C.²⁴⁷ Hyperinsulinemia is most likely responsible for the reduced TK activation, as it is known to inhibit receptor function in other systems.^{58,235,248} By transferring animals to a low-energy diet, it is possible to restore the activation of TK. For complete normalization of TK activity, the return to normoglycemia is not sufficient; the restoration of normoinsulinemia is required. Further studies demonstrated the overexpression of several PKC isoenzymes, particularly of the isoform PKC ϵ .²³⁵ The overexpression and membrane translocation of PKC ϵ appear to contribute to insulin resistance by the inhibition of TK activity through serine/threonine phosphorylation on the receptor and its IRS-1 substrate. In addition, the overexpression of PKC ϵ was associated with attenuation of PKB, an effector of insulin signaling, activating multiple metabolic pathways and partial degradation of the insulin receptor as determined by incubation in human embryonic kidney (HEK 203) cells.²⁴⁹ This finding represents the molecular basis of nutritionally induced insulin resistance in *Psammomys*. It is related to the increase in muscle lipid and diacylglycerol levels, a known activator of several PKC isoforms. This mechanism is supported by findings of an overexpression of PKC ϵ and PKC θ isoenzymes in another model of insulin resistance in the high-fat-fed rat.²⁵⁰

These data show that *Psammomys* is a gerbil adapted to subsistence on low-energy food thanks to its endowment with a "thrifty" gene advantageous to survival. Unfortunately, in many diabetes-prone animals this adaptation is not compatible with lavish food provision, and results in hyperinsulinemia, impaired receptor signaling, and diabetes leading to loss of β -cell function. In this sense, the *Psammomys* is a good model for the study of mechanisms evoking hyperinsulinemia and diabetes in human populations emerging into nutritional abundance.

A novel gene that encodes a small protein has recently been discovered by Collier and colleagues²⁵¹ in the hypothalamus of *Psammomys* and named "beacon." Beacon mRNA gene expression

was positively correlated with percentage of body fat. Intracerebroventricular administration of beacon resulted in a dose-dependent increase in food intake and body weight, and hypothalamic overexpression of neuropeptide Y. Simultaneous infusion of beacon and neuropeptide Y potentiated the orexigenic response and resulted in rapid body weight gain. These novel data suggest a role for beacon and neuropeptide Y in body weight homeostasis.

Acomys cahirinus (Spiny Mice)

These are large mice, with brownish, bristle-like fur, living in semi-arid areas of the eastern Mediterranean, that can attain a weight of up to 50 g on rodent chow in captivity. Interest in spiny mice arose when obesity with islet hyperplasia and hypertrophy were discovered in specimens originating from Israel and maintained in Switzerland on fat-rich bird food of sesame, pumpkin, and sunflower seeds. Low insulin secretory capacity was established as a characteristic of spiny mice.²⁵² The progression of spiny mice to diabetes was characterized by remarkable islet proliferation associated with high insulin content, thought to be compensation for the low capacity of insulin release, with a sudden loss of function at 10–16 months of age, followed by fatal ketosis. Because it took about 40 generations between the transfer to the laboratory and discovery of diabetes, it was suggested by Renold and colleagues²⁵³ that a mutation might have occurred in captivity, causing defective insulin release and compensatory β -cell hypertrophy.

The ultrastructural β -cell features preceding the fulminant diabetes were an overdeveloped Golgi apparatus and gross hypergranulation. This differed from the hypersecretion in other diabetes species, because in spiny mice, plasma insulin levels were only marginally increased and hyperglycemia was mild and intermittent. The low sensitivity of β cells to glucose and other secretagogues was attributed to low islet cyclic AMP response to stimulation, low amounts of vincristine-precipitable microtubular material, and scarce autonomic islet innervation.

To investigate the influence of dietary regimens, the diets of Geneva and Jerusalem strains (which did not exhibit marked β -cell hyperplasia) were exchanged for comparison. The Geneva regimen, including *ad libitum* seeds containing 15% fat, appeared to be the cause of obesity and pancreatic insulin overproduction at 8–10 months, whereas on the Jerusalem diet of regular laboratory chow containing 5% fat, the rise in β -cell insulin and insulin resistance was moderate.²⁵⁴ These studies led to the conclusion that the low insulin response, as well as the obesity, hyperglycemia, and islet hyperplasia seen in spiny mice, is characteristic of a desert species subjected to nutritional stress rather than being due to a monogenic aberration. The low secretory responses of β cells suit the scarce food available in their native habitat, and may be protective against sporadic overstimulation.

On a sucrose-rich diet, spiny mice developed hepatomegaly, hyperactive lipogenesis, and gross hyperlipidemia. Pancreatic insulin content rose, but less so than on the fat-rich seed diet, and no islet disintegration was apparent even at the age of 18 months. The sucrose diet induced an extrathyroidal elevation of triiodothyronine, enhanced thermogenesis, and energy-wasting metabolic reactions.²⁵⁵ This was thought to be protective against excessive weight gain and a disruptive islet cell lesion.

The difference between spiny mice and other models of nutritionally induced diabetes is that spiny mice do not gradually progress to hyperinsulinemia, hyperglycemia, and ketosis. Overnutrition selectively induces β -cell hypertrophy and proliferation

with propensity to disintegration. Perhaps similar mechanisms operate in human low insulin responders when confronted with abundant nutrition.

C57BL/6J Mice

The nonobese, nondiabetic BL/6J mouse, the genomic host of the *ob/ob* mutation, is sensitive to adrenergic stimulation, hypertensive, and insulin resistant, with a weak first-phase insulin release seen at 6 months of age.²⁵⁶ This indicates that abnormalities in the autonomic nervous system, β -cell function, and adipocyte metabolism are responsible for the IGT, and are expressed in BL/6J mice on a high-energy fat- and sucrose-rich diet. There is no hyperphagia or elevation in corticosterone. Genetic mapping has identified differences in the expression of uncoupling protein UCP2 in adipocytes.²⁵⁷ Thus inbred laboratory mice without overt metabolic disturbance reveal environmentally induced diabetes and polygenic vulnerabilities on HE nutrition.

Hypertriglyceridemic (HTG) Rats

The nonobese hereditary hypertriglyceridemic rat is also insulin resistant, deficient in muscle GLUT-4, hyperuricemic, and hypertensive.²⁵⁸ These rats were selected by breeding normal Wistar rats using the hypertriglyceridemic response to a sucrose-rich diet until these symptoms became apparent without nutritional stimulus. The abnormalities were aggravated by continued maintenance on the sucrose-rich diet but were ameliorated by diets rich in ω -3 fatty acids. Enhanced secretion of catecholamines was found.²⁵⁹ The HTG rats, similarly to the C57BL/6J mice, demonstrate a nutritionally induced genetic predisposition for the insulin resistance syndrome.

SELECTIVE INBREEDING OF DIABETIC RODENTS FROM NORMAL POOLS

Apart from animals with spontaneous alterations that lead to inappropriate hyperglycemia and β -cell loss, lines of animals with diabetes have been selected from normal pools by repeated breeding of individuals with minimal deviation from the mean response to a stressful stimulus. These animal lines manifest the requirement for environmental influences to make the genetic predisposition clinically overt, and emphasize the polygenic basis of diabetes which resides within the "normal" genetic mosaic.

Goto-Kakizaki (GK) Rats

Wistar rats have been bred for over 35 generations in Japan, using relative intolerance to a 2-g/kg glucose load as a selection index.²⁶⁰ The 10% of rats within the "hyperglycemic zone" were mated in each generation until the offspring had an IGT at F_{10} and fasting hyperglycemia at F_{35} . The GK rats are nonobese, and their diabetes is inheritable and stable with age. Insulin resistance is present and decreased hepatic insulin receptor numbers were noted with normal TK activity per receptor.²⁶¹ GK rats aroused interest as a model of nonobese T2DM on a polygenic basis. Neuropathy, glomerulopathy, and retinopathy were observed despite only moderate hyperglycemia.

GK islets are oval or round until 2 months of age, and then become irregular and starfish-shaped, apparently due to the accumulation of fibrous material. Insulin secretion in response to glucose is impaired, lacking the first-phase release. However, the progres-

sion to diabetes was also related to the reduced β -cell mass.²⁶² The response of ATP-sensitive K^+ channels to glucose was impaired²⁶³ as was the action of various secretagogues,²⁶⁴ pointing to a dysfunction in glycolytic flux before the glyceraldehyde-3-phosphate step or in the glycerol phosphate shuttle. GLUT-2 was also under-expressed in GK rat islets,²⁶⁵ but not enough to explain the deficient insulin secretion as occurs in *db/db* mice or ZDF rats. The pathogenesis of diabetes in the GK rat has been recently reviewed.²⁶⁶ It should be pointed out that the GK rats in worldwide colonies maintain IGT and low insulin secretion, but other phenotypic properties may differ between the colonies, suggesting genetic drift.

Cohen Sucrose-Induced Diabetic Rat

Cohen and Rosenmann challenged general-stock rats with a copper-poor, 72% sucrose diet to identify individuals with IGT as related in a monograph describing the pathophysiology, complications and genetics of the strain.²⁶⁷ A two-way selection was performed by separate mating of those with highest and lowest glucose tolerance values. The offspring were again subjected to sucrose feeding, and the two-way mating continued, producing Cohen diabetes-sensitive (CDs) and Cohen diabetes-resistant (CDr) lines. After 4–5 generations, the CDs rats had a persistent hyperglycemia of ~ 280 mg/dL (16 mmol/L). The CDr line had normal glucose tolerance even on the sucrose diet. The CDs rats are nonobese, and weigh somewhat less than starch-fed controls even if their food consumption is higher. They are initially hyperinsulinemic, compared with parent rats or the CDr line, which has insulin values lower than the parental stock. The liver enzyme pattern is typical of insulin resistance: The activity of glycolytic enzymes is enhanced, as is that of gluconeogenesis enzymes which are not suppressed by insulin. The insulin response to glucose is low and exogenous insulin produces only a slight effect on blood glucose. With age, the diabetic rats show atrophy of the pancreas with fatty infiltration, and become insulin deficient but not ketotic. The CDs rat was also crossbred with the SHR rat, resulting in a hypertensive, hyperglycemic, and hyperlipidemic hybrid. The Cohen strain was recently newly inbred and the metabolic phenotypes genetically characterized,²⁶⁸ emphasizing its suitability for studies of the interaction between genetic susceptibility and metabolic-nutritional environment as well as the effect of gender on the development of T2DM.

DIABETIC NONRODENTS

A preference has been expressed for animal models other than rodents in diabetes research. The advantage of using large animals is the possibility of performing catheterizations and clamp studies with multiple sampling across organs, as well as long-term longitudinal follow-up of changes and complications that may be not expressed during the short life of rodents. Rodents have a higher rate of metabolic fuel turnover than humans and differ in patterns of growth, but they have the advantage of enabling performance of statistically reliable observations in large cohorts. Ruminants have metabolic, nutritional, and digestive characteristics dissimilar to humans. Other disadvantages include the necessity for protracted care with considerable expenses for facilities and maintenance. It may take years to document the complications of diabetes in dogs or monkeys because they live much longer than rodents, and their life spans are sometimes nearly equal to that of the investigator.

There is also the difficulty with terminal experiments. Thus both nonrodents and rodents offer a wide range of research opportunities, and the choice of a model depends on the specific aims of the investigator.

Primates with Pancreatic Lesions

Howard²⁶⁹ found hyperglycemia without hyperinsulinemia with varying degrees of IGT, weight loss, morphologic and functional β -cell defects, total β -cell loss, and amyloidosis among the Celebes black ape (*Macaca nigra*) and other simian species. Amyloidosis was also seen in other monkey species with overt diabetes including *Macaca fascicularis* and *Macaca radiata*, and a baboon, *Papio anubis*.²⁷⁰ Although amyloid is restricted to islet tissue, it is unknown whether this is the result of a primary reaction or a secondary deposit related to antigen-antibody interaction. However, the islet amyloid content correlates with the intensity of diabetes and the cessation of insulin secretion. Diabetes in these monkeys is severe and associated with hyperlipidemia, xanthomatosis, glucosuria, and ketosis.

The monkey can also develop a type 1 diabetes-like syndrome which progresses over several years. Circulating antibodies to islet cells (ICSAs and ICAs) occur in 80% of macaques with islet dysfunction. Although a correlation between the antibody titers and islet pathology exists, their role in the initiation of insulinitis has not been established. The presence of these antibodies may reflect a response to antigens released from β cells disintegrating as the result of damage by other cytotoxins. The overt diabetes stage is similar to human T1DM, requiring insulin treatment.²⁷⁰

Primates with Obesity and Pronounced Insulin Resistance

Rhesus monkeys (*Macaca mulatta*) in a colony maintained on an *ad libitum* ration develop a type 2 diabetes-like syndrome. Studies spanning many years performed by Hansen and Bodkin and colleagues^{271,272} defined the changes that occur with progression of the disease from leanness to obesity and overt diabetes. Several phases were identified using metabolic and endocrine indices, starting without appreciable elevations of blood glucose and insulin during fasting, but IGT following a glucose load. In phase 4, plasma insulin levels were 161 μ U/mL versus 2 μ U/mL in phase 1. In phases 5 and 6, body weight peaked at $\sim$ 19 kg and plasma insulin at $\sim$ 400 μ U/mL. At this stage the monkeys were leptin resistant.²⁷³ Insulin levels dropped in phases 7 and 8, at which time blood glucose levels were two- to threefold higher than in phase 1. Overt diabetes was prevalent in monkeys 10–20 years old, with pronounced weight loss and β -cell malfunction associated with the deposition of amyloid²⁷⁴ (Fig. 16-4). Hyperinsulinemia in the diabetic obese monkeys was associated with altered muscle insulin receptor mRNA splicing,²⁷⁵ assumed to be related to the nutritionally induced insulin resistance.

Long-term dietary restriction was beneficial in extending the life span²⁷⁶ and preventing diabetes.²⁷⁷ Sedentary lifestyle and obesity in captivity promote the progression to hyperglycemia and β -cell exhaustion. However, IGT with preserved insulin response was found also in 4 out of 30 free-ranging *Macaca fascicularis* in Mauritius, without correlation to age or obesity.²⁷⁸ The phases of diabetes development in monkeys spanning 10–20 years in captivity are reminiscent of those described in *Psammomys*, occurring during several weeks and representing a common effect of surplus energy intake and low energy expenditure.

FIGURE 16-4. Progression of rhesus monkeys (*Macaca mulatta*) to diabetes on an *ad libitum* diet over 12 years. The X axis represents individual monkeys arranged left to right from normal to diabetic. Note that the peak plasma insulin concentrations, indicating oversecretion and resistance, occurred prior to the reduction in the peripheral glucose disappearance rate and the onset of fasting hyperglycemia. The exhaustion of β -cell insulin secretion was associated with amyloid deposition. (Personal contribution of Dr. Barbara C. Hansen.)

Dogs and Cats

The frequency of spontaneous, type 1-like diabetes in dogs of various breeds appears to be 1 in 200.²⁷⁹ Canine diabetes appears to be due to the loss of β cells by a heterogenous autoimmune process,²⁸⁰ or a result of pancreatitis, which is common in dogs. A general inflammatory reaction with extensive sclerosis and fibrosis was evident in the excised pancreas of diabetic dogs of different breeds transplanted with islets obtained from healthy dogs.²⁸¹ An increase in α and δ cells and mononuclear infiltration was seen in the remaining islets, constituting only $\sim$ 10% of the normal β -cell mass. ICAs, ICSAs, and complement-dependent cytotoxicity were not detected, and no islet immunoglobulin deposits were found. These findings demonstrate characteristics different from those of rodents or monkeys. The pancreata were removed months after the onset of diabetes, by which time any evidence of an immune reaction might have disappeared. A multitargeted immune aggression rather than a specific islet-directed autoimmunity is considered likely. Chronic pancreatitis with an immune defect is also plausi-

ble. Extensive studies of retinopathy have been made in spontaneously and experimentally diabetic dogs as well as galactosemic dogs, as reviewed by Kern and colleagues.²⁸²

A defined genetic disorder in keeshond dogs has been reviewed by Kramer.²⁸³ This type 1-like diabetes in nonobese dogs is a spontaneous autosomal recessive disorder with onset at 2–6 months of age. When not maintained on insulin, these dogs become severely hyperglycemic, hyperlipidemic, and ketotic, and develop cataracts and other complications, as well as becoming infertile. Immunocytochemical investigation of the pancreas revealed a specific absence of β cells, but no basis has been found for an autoimmune etiology of the islet lesion.

The incidence of feline diabetes is estimated to be 1 in 800. Little is known about its pathogenesis or genetics. Morphologic changes in islets are minor, but in some early reports hyaline-amyloid deposits were seen.^{279,280,284} Cats exhibit massive deposits of islet amyloid, a product of islet amyloid-associated polypeptide, which is normally coproduced, costored, and most probably co-secreted with insulin, as reviewed by O'Brien and associates²⁸⁵ (see Chaps. 3, 21, and 17). Amyloid may be involved in the pathogenesis of diabetes by impairing insulin secretion in cats and possibly other species.

Cat insulin's structure differs from that of human insulin at four positions, and appears to be the only insulin with histidine at position A18, close to the receptor-interacting area. This suggests that this histidine position in cat insulin may influence the binding of insulin to its receptor.²⁸⁶

CONCLUSION

The animal species with diabetes described in this chapter present an opportunity for investigation of the endocrine, metabolic, and morphologic changes in diverse phenotypic forms of both type 1 and type 2 diabetes. None of the species exhibits the full spectrum of functional or structural lesions associated with diabetes in humans, but each offers an opportunity for investigating certain clusters of derangements that are common in diabetic humans, particularly in their formative stages. A few concluding statements on the lessons learned from the numerous models of type 2 diabetes are appropriate.

A distinction may be made between those endowed with robust β cells with long-lasting secreting capacity that can sustain the huge insulin requirements needed to compensate for the resistance during the entire life span of the animal, and those with labile β cells that fail to compensate for the insulin resistance (Fig. 16-5). The animals of the second group initially oversecrete and present the full picture of typical diabetes. Later their β cells succumb to the pressure of oversecretion and irreversibly necrotize. They are vulnerable to hyperglycemia, either because of the diabetogenic genomic background, or glucotoxicity, or both.

Another feature common to most animal models of T2DM is hyperinsulinemia, which develops early in life, often prior to obesity. This is a result of a hypothalamic aberration that causes hyperphagia by transmitting signals directly to the pancreas through the vagus nerve, or is attributable to the availability of abundant nutrition, or is perhaps due to a low secretion threshold. It should be stressed that the hyperinsulinemia and the hyperglycemia that develop later are the hallmarks of diabetes. When these occur, they signify an advanced stage, with manifest β -cell malfunction. Furthermore, hyperinsulinemia and hyperglycemia are also detrimental by another mechanism. Insulin excess impairs hepatic and mus-

FIGURE 16-5. The inverted U shape of the relation between plasma insulin and glucose levels of several animal species during the development of genetic or nutritionally induced diabetes. The full circles indicate that all listed animals progress to stage B of hyperinsulinemia and obesity. The half-circles in stage C indicate sequential moderate hyperglycemia and remarkable obesity, whereas full circles at stage C indicate pronounced hyperglycemia in *db* mice, male ZDF rats, rhesus monkeys and *Psammomys* gerbils. These four animals progress at varying rates to the endpoint of β -cell loss in stage D, as a result of apoptosis, glucotoxicity, amyloid deposition, or other causes. Other animals continue to oversecrete and compensate for the insulin resistance through the capacity of their β cells to sustain prolonged overstimulation.

cle insulin receptor function by modifying intracellular phosphorylation along the cascade of signaling sequences. One of the most damaging results is the inability to restrain the expression of PEPCK, the rate-limiting enzyme of gluconeogenesis, and this contributes substantially to the hyperglycemia. It is intriguing that in almost all animals with diabetes, the hepatic insulin resistance involves gluconeogenesis, whereas insulin-induced lipogenesis continues to be enhanced, resulting in hyperlipidemia and obesity. By shunting some of the glucose excess to lipids, many of the diabetes species are able to maintain moderate hyperglycemia, but the amelioration of glycemia by this mechanism incurs fat deposition that exacerbates obesity.

Pathology of the Pancreas in Diabetes Mellitus

Per Westermark

As soon as it became clear that the islets of Langerhans play a central role in the development of diabetes mellitus, pathologists focused their interest on this part of the pancreas. Many of the structural islet lesions that we now know to reflect important pathological events in the pancreas were described at an early date.^{1,2} At that time there was no clear distinction between different diabetes mellitus syndromes and although differences between the pathological findings in young and old diabetic individuals were noted, the two diabetes groups were not separated. Only much later was the separation of patients into the syndromes of insulin-dependent or type 1 diabetes mellitus (T1DM) and non-insulin-dependent or type 2 diabetes mellitus (T2DM) performed. We now recognize that the islet pathology in T1DM is very different from the majority of individuals with T2DM. Most recently, distinctive but rare forms of diabetes mellitus have been described, such as familial insulinopathies³ and maturity onset diabetes of the young (MODY). It should be pointed out that many studies of human islet pathology are based on autopsy materials that may not be completely clean (i.e., they may include cases misinterpreted as either type 1 or type 2). The considerable overlap between T1DM and T2DM concerning islet or β -cell volume may partially depend on this problem.

This chapter deals primarily with the pancreatic pathology of type 1 and type 2 diabetes. Some pathogenetic aspects of these syndromes are also discussed. Comparably little is known about the pancreatic pathology in the rare forms of diabetes.

PANCREAS IN T1DM

General

In recent onset type 1 diabetes, no significant reduction of pancreatic size is found.^{4,5} In long-standing T1DM, there is often, but not always, a significant reduction of pancreatic weight⁴⁻⁷ accompanied by interstitial fibrosis of the exocrine tissue.^{6,8} However, the weight reduction only affects the pancreatic peptide (PP)-poor part of the pancreas.⁸ Arteriosclerotic and arteriolosclerotic changes are very common in long-standing T1DM and are often pronounced.^{5,6} These may lead to secondary changes such as local atrophy and pronounced fibrosis.

Islet Cells and Islet Cell Volume

Even in recent onset T1DM, there is often a reduction in the number of islets^{5,6} but in quantitative studies, there is considerable overlap with the normal pancreas.⁹ A reduction of β -cell granula-

tion is often conspicuous.⁹ Even in islets from individuals with a very brief history of T1DM, the number of β cells is greatly reduced, the majority of islets being devoid of them.^{5,10} These so-called pseudoatrophic islets, like islets in long-standing T1DM, consist of α -, δ and PP cells, and thus are devoid of insulin (and islet amyloid polypeptide; IAPP). The islets are composed of cords of small cells (Fig. 17-1). Islets consisting entirely of PP cells increase in frequency with the duration of T1DM,¹⁰ but there is no demonstrable increase of the volume density of PP cells.⁸ In long-standing type 1 diabetes, the islets are small¹¹ and there is a major reduction of islet volume,^{4,5,7} which is caused largely by the nearly complete lack of islet β cells.⁵ This β -cell atrophy coincides well with the very small amount of extractable insulin in such pancreata.¹² In spite of the pronounced β -cell loss, a few β cells are commonly found in many cases of type 1 diabetes of long duration. A decrease in α -cell volume has been found in one study.⁷

Inflammatory Cell Infiltrate (Insulitis)

Infiltration of the islets with mononuclear inflammatory cells (insulitis or isletitis) (Fig. 17-2) is a common finding in T1DM of recent onset,^{4,5,12} especially in children under 10 years of age.⁹ In pancreatic material from 16 young persons who had had diabetes for only a few days, Gepts and De Mey found islets with lymphocytic infiltration in 9.¹⁰ However, in specimens of pancreatic biopsies from 17 individuals with recent onset of T1DM, Imagawa and colleagues found insulitis in only 9, and concluded that there may exist at least two mechanisms for β -cell death.¹³ Insulitis has also been described rarely in late-onset diabetes in conjunction with islet amyloid.¹⁴ In cases of T1DM of longer duration, insulitis may be absent.^{5,10} When present, the inflammatory infiltrate consists mainly of T lymphocytes, B lymphocytes and macrophages.¹⁵ T lymphocytes predominate and there are usually more CD8 T cells than CD4 T cells,^{13,16} although the opposite has been found in isolated cases.¹⁷

Lymphocytic infiltration occurs only in islets with β cells and is seen in at least 80% of pancreata of individuals who have been studied at the clinical onset of T1DM.¹⁶ In type 1 diabetes of recent onset, three main types of islets have been described: apparently normal islets, inflamed islets, and pseudoatrophic islets, which are devoid of β cells but contain all other islet cell types.^{5,15} There is reason to believe that these different islet forms reflect a pathologic chain of events and that many islet abnormalities are present long before the clinical onset of diabetes. The end result may be the so-called pseudoatrophic islet.

FIGURE 17-1. Islet from the pancreas of a patient with long-standing T1DM. The islet is small and consists of cords of cells, mainly α cells ($\times 475$).

By studying patients that have undergone pancreas transplantation for the treatment of T1DM, evidence has been obtained of the pathogenic importance of the inflammatory infiltrate in β -cell destruction. Some such patients have had recurrence of their diabetes, and in association with this, insulinitis similar to that seen in recent onset type 1 diabetes has been found.¹⁸ However, recurrent type 1 diabetes and β -cell loss without signs of insulinitis in the transplant has also been recorded.¹⁹

During recent years it has become evident that some individuals, previously believed to have T2DM in reality are suffering from late onset T1DM. Understandably, few studies of the pancreatic pathology have been performed on such cases. In a pancreatic biopsy from one such individual with "latent autoimmune diabetes in adults," typical insulinitis with CD4⁺ and CD8⁺ T cells was identified.¹⁷

Expression of Major Histocompatibility Complex

Like all other cells, islet epithelial cells normally express class I MHC. However, in recent onset type 1 diabetes there is a hyper-

FIGURE 17-2. Heavy infiltration of an islet with lymphocytes from a patient with recently diagnosed T1DM ($\times 500$). (Reproduced, with permission, from Volk BW: *Pathology of the diabetic pancreas*. In: Porte D, Sherwin R, eds. *Ellenberg & Rifkin's Diabetes Mellitus*, 4th ed. Appleton & Lange; 1988.)

expression of class I MHC in α , δ , and β cells,^{13,20,21} which disappears in the pseudoatrophic islets, and which is not seen in other chronic inflammatory pancreatic disorders. There is also an α -interferon-like immunostaining of β cells in these islets.²² Expression of Fas occurs in endocrine cells, mainly β cells, in many islets with insulinitis, and inflammatory cells expressing Fas ligand may be found in the same islets, possibly indicating Fas-mediated apoptotic β -cell death.²³ Aberrant expression of class II antigen in some β cells has also been reported in recent onset T1DM.^{15,20} The importance of the hyperexpression of class I MHC and aberrant expression of class II MHC in the autoimmune process is not fully understood. However, both events are believed to precede the insulinitis and to be involved in its pathogenesis.²¹

Islet Regeneration

Signs of β -cell regeneration are common in recent onset type 1 diabetes. Small new islets appear to differentiate from exocrine ducts and consist of hyperactive β cells.¹⁰ Such islets can also become targets of lymphocytic infiltration.

Other Islet Lesions

Some degree of islet fibrosis is common. Islet amyloidosis is absent in T1DM. In spite of this, there are a few reports of islet amyloidosis in young individuals with diabetes, and this includes Opie's original description.¹ The nature of the amyloid as well as the exact type of diabetes in these patients is not clear.

PANCREAS IN T2DM

General

Since type 2 diabetes is a disease of slow onset, it is difficult to distinguish a definite time of onset of the disease. Therefore very little is known about the early pancreatic pathology of T2DM in humans. Such studies have to be performed in animal models of type 2 diabetes.^{24,25}

In contrast to T1DM, the pancreas in T2DM is usually of normal size^{7,11,26} but with a tendency toward fatty infiltration,²⁶ most probably due to the obesity present in many of these patients. Arteriosclerotic changes, often severe, are the rule, and diffuse or focal fibrosis is common.

Islet Cells and Islet Cell Volume

There are several studies showing a moderate reduction of the total islet volume in T2DM.^{7,26} This reduction is mainly due to a reduced β -cell mass,^{7,27} reflected by a significantly lower relative islet β -cell frequency in type 2 diabetes.^{11,28,29} However, there is a significant overlap between nondiabetic and diabetic elderly individuals in both islet volume and percentage of islet β cells,^{26,28} and in one study no significant islet volume reduction was found.¹¹ A pronounced β -cell loss as seen in T1DM does not occur in T2DM. Furthermore, the β cells in type 2 diabetes are rich in granules and not degranulated as in type 1 diabetes. In one study, densitometric studies of insulin immunolabeled sections did not reveal any difference between diabetic and nondiabetic individuals.³⁰ There are contradictory results concerning the α -cell mass in T2DM, with both reduced α -cell mass,^{7,27} and increased α -cell mass¹¹ reported. In a majority of individuals, many of the islets show pathological

alterations, particularly amyloid deposits. The shape of the islets is often more irregular in T2DM³⁹ and enlarged islets occur in cases with islet amyloidosis.³¹ Hyperproinsulinemia is a typical feature of T2DM. In one immunohistochemical study with proinsulin antibody, an increase in β cells with signs of impaired proinsulin processing was found in obese, but not in lean, type 2 diabetic pancreatic islets.³⁰ Proinsulin gene expression was decreased in β cells in amyloid-containing islets as compared to islets without amyloid.³⁰

Islet Hyperplasia

Hyperplasia of islet cells resulting in marked islet hypertrophy has been reported in one study of pancreatic specimens from nondiabetic obese individuals,³² and in another study the β -cell volume in obese type 2 diabetic patients was twice that of nonobese diabetic individuals.³³ Obese, nondiabetic individuals had the greatest β -cell volume, which was four times that of nonobese diabetic subjects.

Islet Regeneration

Signs of islet regeneration have sometimes been described in type 2 diabetes. However, the volume distribution of islets is usually normal in T2DM (except for islets with heavy amyloid infiltration), suggesting that there is no significant regeneration of whole islets.³¹

Islet Amyloid

It has sometimes been stated that the pancreas (including the islets) is morphologically normal in T2DM. Nevertheless, the most typical and frequent lesion, deposition of amyloid in the islets of Langerhans, was described independently in two articles at the beginning of the 20th century.^{1,2} Although the similarity to amyloid was pointed out early,³⁴ the deposited material was first described as hyaline, and it was not until the green birefringence under polarization microscopy after Congo red staining was recognized and the fine fibrillar ultrastructure demonstrated that the amyloid nature of the deposits was accepted.^{35,36}

Frequency of Islet Amyloid

Some degree of islet amyloidosis is found in a majority of type 2 diabetic patients. The frequency varies among studies. Bell³⁷ reported some degree of islet amyloidosis in 46% of diabetic patients over 50 years of age. In our own material, 95% of T2DM patients over 60 years old exhibited some degree of islet amyloidosis, but in some modern materials a low frequency (57%) has also been reported.³⁰ The differences in the frequency of islets with amyloid among studies is probably due to methodological variations; also, the degree of islet amyloidosis is easily underestimated. The frequency of islets with amyloid deposits is higher in the pancreatic tail and body compared to the head,³⁸ and the distribution of affected islets is often uneven. Sometimes, lobuli with pronounced islet amyloid deposits may be found, while other parts of the pancreas contain no or little amyloid.

Some islet amyloid deposits are also commonly found in nondiabetic individuals.^{38,39} In these subjects, the number of affected islets is generally much smaller and the degree of islet amyloidosis is significantly less. There are, however, examples of severe islet amyloidosis in nondiabetic individuals.^{38,39} It is possible that these individuals in reality suffered from undiagnosed T2DM.

FIGURE 17-3. Islet from a patient with T2DM. The islet is heavily infiltrated with amyloid, which constitutes more than 50% of the islet volume. In this section, residual endocrine cells appear as cords in the amyloid masses ($\times 225$).

Structure and Topography of Islet Amyloid

Islet amyloid is strictly localized to the endocrine tissue and is not seen in the exocrine tissue (Fig. 17-3). In individuals with slight degrees of islet amyloidosis, the lesion appears as small deposits in the interstitium between islet cells and capillaries, or as a thin amyloid deposit covering the capillary side of the endocrine epithelial cell groups. With more pronounced deposition, islets can become more or less converted into amyloid lumps (Fig. 17-3), although some β , α , and δ cells almost always remain. Ultrastructurally, like all types of amyloid, islet amyloid is composed of thin non-branched fibrils 7–10 nm in diameter (Fig. 17-4). In the larger deposits, these fibrils form a disorganized network, while in small fibril aggregates and in deposits close to β cells, the amyloid fibrils

FIGURE 17-4. Typical islet amyloid fibrils forming a disorganized network. The section was labeled with antiserum to islet amyloid polypeptide (IAPP) and the reaction visualized with protein A-gold particles. The amyloid fibrils (A) react with the antiserum to IAPP, but the collagen (C) does not ($\times 50,000$).

FIGURE 17-5. Electron photomicrograph showing the periphery of β cells containing many typical granules. Amyloid (A) is seen extracellularly as parallel bundles in deep plasma membrane-lined pockets of the cells ($\times 54,000$).

tend to form parallel bundles (Fig. 17-5). Such bundles are often seen in deep cytoplasmic membrane-lined pockets in the β cells, but not in other cells.⁴⁰ This close relationship between islet amyloid and β cells has been interpreted as a sign of formation of fibrils from a protein produced by these cells.⁴⁰

There is some controversy regarding the exact site of islet amyloid formation. Virtually all islet amyloid is found extracellularly, even in cases with very slight (and therefore probably early) deposits.⁴⁰ Formation of the fibrils extracellularly, but in close contact with β cells, has been suggested.⁴¹ However, intracellular formation of the amyloid has also been proposed⁴² and studies of amyloid formation in human islets transplanted into nude mice⁴³ and electron microscopic studies of human insulinomas⁴⁴ have supported this supposition. Given the concept that amyloid formation is a nucleation-dependent process, it is possible, but not proven, that the first amyloid forms intracellularly by mechanisms yet to be clarified. The main bulk of amyloid may then be formed extracellularly on the amyloid originally formed, after the death of the cell containing the first amyloid.⁴⁵

Pathogenic Importance of Islet Amyloid

Islet amyloid was long regarded as a characteristic islet lesion of type 2 diabetes, but was thought to be of no pathogenic importance. Study of the phenomenon is difficult in humans, and investigations in the relationship between islet amyloid and diabetes in the primate *Macaca nigra*⁴⁶ and the domestic cat⁴⁷ were largely disregarded. However, recent experiments with transgenic mice expressing human IAPP have changed this view since a close relationship between glucose intolerance or diabetes and occurrence of islet amyloid deposits has been shown repeatedly in such animals (see Chap. 21).⁴⁸⁻⁵⁰ Whether islet amyloid is of initial importance in the pathogenesis of type 2 diabetes is thus far uncertain, but there is a growing consensus that islet amyloid is important in the continuing deterioration of β -cell function in type 2 diabetes.^{50,51} Beta cells in contact with even small deposits of islet amyloid show signs of degeneration, with parallel bundles of fibrils running through the basement and cell membranes.⁴⁰ In islets with more heavy deposition, severe β -cell degeneration occurs. It is rea-

sonable to assume that β -cell function is impaired in such cases, both by direct destruction of the cells and by the barrier formed by the amyloid masses.²⁶ There is also experimental evidence that IAPP amyloid fibrils, like A β -protein fibrils in Alzheimer's disease, exert a cytotoxic effect by a yet unknown mechanism.^{52,53} There is also evidence that the most toxic species are not fully developed amyloid fibrils, but the initially formed "protofibrils"⁵⁴ (see below). Since severe islet amyloidosis occurs more often in patients who have been treated with insulin,^{55,56} it is probable that islet amyloid at least partly explains secondary failure in the treatment of type 2 diabetes with oral hypoglycemic drugs. It should be mentioned, however, that not all investigators believe in the pathophysiologic importance of islet amyloid deposits.³⁰

Nature and Pathogenesis of Islet Amyloid

All types of amyloid fibrils are polymers of small proteins, with one specific protein characteristic of each amyloid form.⁵⁷ Several polypeptide hormones are known to give rise to local amyloid deposits.⁵⁸ Islet amyloid has as a major constituent islet amyloid polypeptide (IAPP; amylin),⁵⁹ which is a 37-amino-acid polypeptide related to the neuropeptide calcitonin gene-related peptide (CGRP) (Fig. 17-6).^{60,61} IAPP is mainly expressed by islet β cells as a 89-amino-acid prepolypeptide of which a 22-amino-acid leader sequence is cleaved off initially. The 67-amino-acid proIAPP is converted to mature IAPP by cleavage at two basic amino acid residues flanking the IAPP sequence. IAPP is stored with insulin in the secretory granules⁶² and the two peptides are released together. However, on a molar basis, the ratio of IAPP to insulin is less than 1:10 in islets and plasma.

The physicochemical mechanisms by which amyloid fibrils form are likely similar among the different biochemical forms of amyloid, and include adoption of a beta sheet secondary structure

FIGURE 17-6. Human islet amyloid polypeptide is a 37-amino-acid C-terminally amidated peptide. For full biologic activity, IAPP requires a disulfide bond between residues 2 and 7 and the C-terminal amidation.

FIGURE 17-7. Fibrils formed from synthetic human IAPP. These fibrils resemble the native islet amyloid fibrils in size and staining properties ($\times 60,000$).

of the protein.⁶³ The beta strands are arranged perpendicularly to the fibril axis, allowing strong intermolecular noncovalent bonding. There is a growing body of research indicating that very thin "protofibrils" form first and that these subsequently assemble to make up the mature fibrils.^{63,64} These protofibrils, which may be the most significant in causing β -cell injury, usually escape detection with ordinary electron microscopic studies and may well be present in islets apparently free of amyloid.

Human IAPP, like IAPP in other primates and in cats, has a strong intrinsic fibril-forming tendency (Fig. 17-7). In contrast, IAPP of most other animal species does not form fibrils due to interspecies amino acid substitutions in the 20-29 segment of the molecule⁶⁵⁻⁶⁷ (Fig. 17-8).

It is not known why IAPP forms islet amyloid in T2DM, although an overexpression of the peptide may be of importance. However, transgenic mice overexpressing human IAPP do not readily form islet amyloid, indicating that additional factors are of importance. Free fatty acids may induce altered expression, processing, storage or release of IAPP.⁵¹ Beta cells of islets with amyloid contain little or no IAPP immunoreactivity^{68,69} in spite of near normal insulin immunoreactivity and the presence of IAPP mRNA

FIGURE 17-8. The 20-29 segment of human CGRP and of IAPP from four species. The sequence differences help to explain why only certain species like humans and cats develop islet amyloid, while others such as mice and hamsters do not. The symbol (—) indicates identity with human IAPP 20-29. Note the complete lack of identity in the 20-29 segments of human CGRP and IAPP.

Human IAPP20-29	SNNFGAILSS
Cat IAPP20-29	---L-----P
Mouse IAPP20-29	---L-PV-PP
Hamster IAPP20-29	N--L-PV--P
Human CGRP20-29	GGVVKNNFVP

in IAPP-negative islet cells.⁷⁰ This lack of immunoreactivity is not due to depletion of (pro)IAPP in the β cells, but IAPP seems to be present in the cells in an abnormal, as yet undefined form.⁷¹

Islet amyloid contains, like all other types of amyloid, several additional components that are always present. Thus the glycoprotein amyloid P component (SAP), which is a plasma pentraxine protein, is a constituent of islet amyloid. Proteoglycans, especially the heparan sulfate proteoglycan perlecan, is present in islet amyloid⁷² and the glycosaminoglycan moiety is the reason why the amyloid can be histologically stained with anionic dyes such as alcian blue.⁷³ Apolipoprotein E (apo E) has been of considerable interest in the pathogenesis of A β -amyloid in Alzheimer's disease, and one allelic form (apoE4) is a risk factor for late-onset Alzheimer's disease. Apo E has also been shown to be a component of human islet amyloid.^{51,74} The importance of these additional components in the pathogenesis of the amyloid fibrils is unknown at present, but it has been suggested that they may stabilize a fibrillogenic protein conformation and thereby function as "pathological chaperones."⁷⁵

DIABETES MELLITUS SECONDARY TO PANCREATIC DISEASE AND OTHER RARE FORMS OF DIABETES MELLITUS

Diabetes mellitus commonly occurs in patients with chronic pancreatitis, cystic fibrosis, and hemochromatosis. In all these diseases, the exocrine parenchyma is primarily destroyed, leading to severe fibrosis. Islet atrophy with fibrosis occurs later and is usually not as severe as that of the exocrine parenchyma.⁷⁶ The presence of iron in some islet β cells seems to play an important role in the development of diabetes in hemochromatosis.⁷⁷ These rare forms of diabetes are not associated with islet amyloidosis. A type of diabetes resembling type 2 diabetes commonly develops in conjunction with pancreatic carcinoma.⁷⁸ Although the tumor often causes widespread destruction of pancreatic tissue, loss of islet tissue is not a major cause of the diabetes, since partial pancreatectomy often improves the diabetic state.⁷⁹ The pathogenesis of this tumor-associated diabetes form is therefore unknown.

Other rare forms of diabetes mellitus about which little is known of the pancreatic pathology include insulinopathies³ and maturity onset diabetes of the young (MODY). In patients with diabetes associated with a mutation in mitochondrial DNA, Orabe and colleagues found a reduced number of β cells but no insulinitis.⁸⁰

Classification and Diagnosis of Diabetes Mellitus

Silvio E. Inzucchi

Diabetes mellitus is a common metabolic disease characterized by increased circulating glucose concentrations associated with abnormalities in carbohydrate, fat, and protein metabolism, and a variety of microvascular, macrovascular, neurologic, and infectious complications. In stark contrast to the consistency in these cardinal manifestations is a significant variability in its etiopathogenesis. An appreciation of the myriad causes of diabetes is aided by a thorough understanding of the homeostatic mechanisms serving to maintain extracellular glucose concentrations within a specified normal range. These are comprehensively reviewed in Chap. 1. Briefly, in the absence of disease, plasma glucose concentrations during fasting are kept within tight physiologic boundaries through the effects of insulin, the hormone governing intermediary metabolism. During fasting, low circulating insulin concentrations serve to modulate endogenous glucose production, primarily of hepatic origin. This effect is counterbalanced by a variety of other regulatory hormones, chiefly glucagon. In the postprandial setting, ingested carbohydrates are absorbed from the gastrointestinal tract. The resultant tendency for glucose concentrations to rise is blunted by an abrupt increase in pancreatic insulin secretion, shutting off hepatic glucose production and simultaneously augmenting glucose disposal into peripheral tissues, such as muscle and fat as well as the liver. Perturbations in this finely regulated system may result in hyperglycemia.

All diabetic states result from an inadequate supply of insulin or an inadequate tissue response to its actions. The former occurs in, for example, type 1 diabetes, which culminates from the autoimmune destruction of the insulin-producing β cells within the pancreatic islets. The latter occurs when the insulin receptor is defective, or, more commonly, when genetic and/or acquired defects in postreceptor intracellular signaling pathways attenuate the subsequent physiologic response. Such is the case with the more widely prevalent type 2 diabetes, a complex disorder resulting from peripheral insulin resistance, combined with relative insulin deficiency.

In this chapter, the currently accepted clinical classification of diabetes mellitus, the categorization of progressive stages of abnormal glucose homeostasis, and the available diagnostic tests that are commonly used to make these distinctions are reviewed and placed into historical perspective. Distinguishing normality from disease is an ongoing challenge in many areas of endocrinology, and the reader should keep in mind that classification schemas and numerical diagnostic thresholds will always be, in part, artificial constructs emanating from the desire to partition individuals and the conditions that afflict them. Nonetheless, they provide an important framework upon which patients and diseases can be diagnosed, treated, and studied.

ETIOLOGIC CLASSIFICATION OF DIABETES

Not a single disease, diabetes is a heterogeneous group of disorders related to each other only because of their primary manifestations: hyperglycemia and resultant vascular complications. In the past, when the understanding of underlying pathophysiologic mechanisms was less mature, its classification was based on either the age groups affected¹ or on conventional treatment paradigms.^{2,3} For instance, the currently designated type 1 diabetes mellitus was referred to as “juvenile-onset diabetes mellitus (JODM)” or “insulin-dependent diabetes mellitus (IDDM),” while type 2 diabetes mellitus was labeled “adult-onset diabetes mellitus (AODM)” or “non-insulin-dependent diabetes mellitus (NIDDM).” As knowledge regarding the underlying cellular and even molecular underpinnings of diabetes has matured, a more pathophysiologically based nomenclature has developed. See Table 18–1 for the etiologic classification schema currently accepted by both the American Diabetes Association (ADA)⁴ and the World Health Organization (WHO).⁵

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus (T1DM) is responsible for approximately 5–10% of all cases of diabetes in the Western world. It is characterized by severe insulin deficiency resulting from β -cell destruction. Ultimately, circulating insulin concentrations are negligible or completely absent. When the disease is fully expressed (and in the absence of insulin therapy), patients with T1DM exhibit not only hyperglycemia but are also ketosis-prone. Thus, these individuals are “dependent” on insulin for survival. β -Cell destruction in T1DM is autoimmune in nature. Islet inflammation (“insulinitis”) may be seen in pathologic pancreatic specimens from individuals prior to the development of diabetes. Once hyperglycemia and insulin dependence are well established, however, selective loss of β cells may be the only histologic abnormality (Chap. 20).

As with most autoimmune diseases, T1DM is associated with genes within the major histocompatibility complex (MHC). The prevalence of certain histocompatibility locus antigens (HLAs) is either increased (DR3, DQ2 or DR4, DQ8) or decreased (DR2, DQ6).⁶ One or several immune response or other genes are likely to enhance the effect of these HLA antigens, rendering the patient at increased susceptibility to β -cell injury, through the interaction of one or several environmental factors. The presence of islet cell injury in patients with T1DM is reflected in certain circulating antibodies, such as islet cell antibodies (ICAs), insulin autoantibodies (IAAs), and antibodies to glutamic acid decarboxylase (GAD) and

TABLE 18-1. Etiologic Classification of Diabetes Mellitus

Type 1 (formerly insulin-dependent diabetes, IDDM)
Beta-cell destruction, resulting in absolute insulin deficiency.
Autoimmune
Idiopathic
Type 2 (formerly non-insulin-dependent diabetes, NIDDM)
Variable disorder ranging from predominately insulin resistance with relative insulin deficiency to a predominately insulin secretory defect with or without insulin resistance.
Other specific types (secondary diabetes)
Genetic defects of β -cell function (i.e., MODY)
Genetic defects of insulin action
Diseases of the exocrine pancreas
Other endocrinopathies
Drug- or chemical-induced
Infections
Uncommon forms of immune-mediated diabetes
Other congenital syndromes associated with diabetes
Gestational diabetes
Diabetes diagnosed during pregnancy, with usual resolution postpartum.

ICA512 (or IA2).⁷ Type 1A diabetes refers to the form that is associated with such immune markers, although it should be noted that as permanent islet cell destruction is established, antibody titers may dissipate or disappear entirely. A less common second subtype, Type 1B, is idiopathic in origin, and may not have an immune-mediated etiology.⁴

Although the islet autoimmunity can precede clinical manifestations of disease by years or even decades, the presentation of T1DM is often abrupt and severe because of the eventuation of a loss of a critical mass of insulin-producing cells. The clinical onset of T1DM is marked by hyperglycemia developing over several days to weeks, usually associated with weight loss, fatigue, polyuria, polydipsia, blurring of vision, and evidence of volume contraction. The presence of ketoacidosis indicates the severe deficiency of insulin, which leads to both the hyperglycemia as well as unrestrained lipolysis. In this setting, increased circulating concentrations of free fatty acids provide substrate to the liver for the accelerated production of ketones (as well as energy for gluconeogenesis). Ketone clearance by the kidneys is reduced due to volume contraction. The result is hyperketonemia, and an anion-gap metabolic acidosis. If uncorrected, the dehydration and acid-base disturbance will lead to further electrolyte abnormalities, cardiac dysrhythmias, hemodynamic collapse, and, ultimately, death.⁸

T1DM is usually diagnosed prior to the age of 30–40 years, most commonly in childhood or in adolescence. However, T1DM occurs throughout life and is often misdiagnosed as T2DM when it appears after the age of 40 years. Individuals with T1DM are typically lean, although the presence of obesity certainly does not preclude the diagnosis. Despite the genetic predisposition for T1DM, most affected patients, in contrast to type 2 diabetes, have no family history of diabetes.

T1DM, particularly when poorly controlled, predisposes patients to microvascular diseases, such as retinopathy and nephropathy; atherosclerosis, resulting in cardiovascular, cerebrovascular, and peripheral vascular disease; neuropathy; complications during pregnancy; and infection.

Type 2 Diabetes Mellitus

In many ways, type 2 diabetes mellitus (T2DM) is an entirely separate disorder from T1DM. It is a much more common condition, responsible for more than 90 percent of cases of diabetes worldwide. The autoimmune markers of type 1 diabetes are typically absent. While relative beta-cell insufficiency is, by definition, present in all individuals with T2DM, the disorder in most is characterized by insulin resistance detected at the level of skeletal muscle, adipose tissue, and the liver.⁹ Insulin resistance at the former site results in decreased peripheral glucose disposal, while at the latter, in increased hepatic glucose production. Unlike T1DM, a family history is common, although the inheritance pattern of this disease is complex and suspected to be polygenic (Chapters 21 to 24).

In many individuals, the natural history of T2DM begins with a period of insulin resistance with preserved, indeed augmented, pancreatic insulin secretion, as the insensitivity to insulin action in peripheral tissues is overcome by hyperinsulinemia.¹⁰ As a result, plasma glucose concentrations remain relatively normal. As the disease progresses, however, pancreatic islet cell function falters and is no longer able to meet peripheral demands. As a result, insulin levels fail to keep up with requirements, and hyperglycemia ensues. This may be first manifested in the post-prandial setting, while fasting glucose is preserved early in the disease course. Even in those with late-stage T2DM, insulin secretion persists to an extent required to suppress lipolysis in most patients, so that ketoacidosis rarely occurs. Ketosis can develop, however, when an intervening medical illness poses a severe metabolic stress, further heightening insulin resistance and impairing the insulin secretory response. Because of renal glucose clearance, plasma glucose concentrations in T2DM typically plateau in the 250 to 350 mg/dL range. However, in the presence of any superimposed deterioration in renal function or marked dehydration, further elevations may occur. Hyperosmolar, hyperglycemic nonketotic (HHNK) coma can result and can be life-threatening.⁸

Compared to patients with T1DM, those with T2DM are typically older, usually over 40 years, and are commonly overweight, if not frankly obese. Over the past decade, however, a frightening increase in the prevalence of T2DM has been noted in younger age groups, even in children.¹¹ This is felt to result from increasing rates of obesity and inactivity in populations from certain ethnic groups predisposed to T2DM, including Native, African, and Hispanic Americans, and Pacific Islanders.

In patients with or at risk for T2DM, a group of other clinical and biochemical characteristics is frequently encountered. These include central obesity, hypertension, dyslipidemia (elevated triglycerides, decreased HDL-cholesterol, and increased small dense LDL-cholesterol), a procoagulant state, endothelial dysfunction, and an increased risk for premature cardiovascular morbidity. This constellation of findings is often referred to as the metabolic syndrome (formerly, syndrome X). Insulin resistance is felt by many to be the root cause of this complex, and, thus, many refer to it as the "insulin resistance syndrome."¹² The striking predisposition of patients with T2DM to cardiovascular disease, even prior to their development of significant hyperglycemia, may result from the combined effects on the vasculature of these manifestations.

While patients with T2DM can use insulin for blood glucose control, they rarely require it to avoid the life-threatening complications of ketoacidosis. Importantly, however, when insulin is required for optimal blood glucose control, the designation of disease

type is not changed. It should also be noted that some adult individuals with diabetes mellitus, usually between the ages of 20 and 40 years, share features of both type 1 and type 2 disease and, as a result, escape easy categorization. These individuals are often leaner and more insulin deficient than those with classical T2DM. Frequently, immune markers of T1DM are present, and their hyperglycemia appears to represent a slowly progressive form of autoimmune diabetes. Furthermore, it has recently been discovered that as many as 10 percent of elderly patients classified as T2DM may also have measurable titers of autoantibodies associated with T1DM. Similarly, these patients may also have a slowly evolving form of T1DM, which is now referred to as "latent autoimmune diabetes of adulthood (LADA)."¹³ T2DM predisposes patients to the same microvascular, macrovascular, developmental, and infectious complications associated with T1DM.

Other Forms of Diabetes Mellitus (Secondary Diabetes)

Several forms of diabetes result from or are related to another specific disease process or genetic disorder. According to current classifications, these conditions are considered neither T1DM nor T2DM and are grouped together under "other specific types," sometimes referred to as "secondary diabetes."^{4,5} This category represents a variety of conditions that are included because of (1) a recognized comprehension of the underlying pathogenesis; (2) the molecular defects governing the hyperglycemia are well defined; or (3) a clear association between the diabetes and an otherwise precisely defined clinical syndrome. These somewhat disparate criteria for inclusion in this category highlight the lack of understanding of the etiologic mechanisms involved in the far more prevalent T1DM and T2DM. It is quite likely, however, that over the next decade, many forms of diabetes currently classified under these broad umbrellas will have their etiologies better defined and be recategorized into this other designation. More likely, as knowledge in the areas of molecular medicine and genetics continues to explode, the classification of diabetes may at some point be completely transformed. At this time, however, this category of diabetes includes genetic disorders of β -cell function and insulin action; inflammatory, infiltrative, and neoplastic diseases of the pancreas; diabetes resulting from other endocrinopathies or infectious diseases, or the use of certain medications or exposure to certain chemical agents; rare forms of immune-mediated diabetes; and a variety of other congenital syndromes frequently associated with hyperglycemia.

Genetic Defects in β -Cell Function

Maturity onset diabetes of the young (MODY) is a clinically heterogeneous group of hyperglycemic disorders with an autosomal dominant mode of inheritance that may account for 1–5% of diabetes cases in the United States. Patients with MODY are usually not obese and may be mildly hyperglycemic. They are generally not predisposed to ketoacidosis. The onset of disease is typically before age 25 years, usually in childhood or adolescence, although the mild nature of the disorder may mask clinical detection for many years. There is a strong family history of diabetes in multiple generations (Chap. 21). Primary defects in β -cell function, which are becoming well defined, appear to be responsible for all cases of MODY. To date, six separate genetic mutations have been characterized and numbered, MODY 1 through MODY 6. The mu-

tated gene in MODY 2 encodes for glucokinase, a glycolytic enzyme. The remaining genes encode for a variety of transcription factors: hepatocyte nuclear factor-4 α (HNF-4 α) in MODY 1, HNF-1 α in MODY 3, insulin promoter factor-1 (IPF-1) in MODY 4, HNF-1 β in MODY 5, and neurogenic differentiation factor 1 (NeuroD1) (or beta-cell E-box transactivator 2 (BETA2) in MODY 6.¹⁴ MODY 3 has the highest prevalence rate, and MODY 2 is the next most common form of the disorder. Each of these genes is expressed in islets and their mutations result in abnormal glucorecognition by the β cell, or in insulin secretory dysfunction, or both. Although uncommon, understanding MODY, particularly the mechanisms that attenuate insulin secretion, has led to a better understanding of pancreatic endocrine dysfunction in T2DM.

Genetic Defects in Insulin Action

Abnormalities of the insulin molecule or its receptor can lead to diabetes, but these are extraordinarily rare conditions that are manifested in infancy. Leprechaunism, which results from an inactivating mutation in the insulin receptor, for example, is characterized by severe insulin resistance, dysmorphic features, intrauterine growth retardation, and acanthosis nigricans. Other forms of diabetes in this category include type A insulin resistance with acanthosis nigricans, Rabson-Mendenhall syndrome (dental dysplasia, dystrophic nails, precocious puberty), and lipodystrophic diabetes. More recently, genetic mutations in the nuclear transcription factor known as PPAR- γ (peroxisome proliferator-activated receptor- γ) has been associated with severe insulin resistance and diabetes (Chap. 21).¹⁵

Exocrine Pancreatic Diseases

Diseases of the nonislet pancreas are also frequently associated with abnormalities of glucose tolerance. Hyperglycemia can be a sequela of both acute and chronic pancreatitis, as well as other diseases that involve the pancreatic parenchyma, such as hemochromatosis and cystic fibrosis. In the tropics, malnutrition-related fibrocalculous pancreatitis has been linked to diabetes.¹⁶ Hyperglycemia is also commonly encountered in patients with carcinoma of the pancreas.

Other Endocrinopathies

Other hormonal disorders are frequently associated with glucose intolerance and sometimes, frank diabetes (Chap. 25). Most of these involve the secretion of counterregulatory factors, leading to a state of decreased insulin sensitivity. Glucose intolerance is seen in 50% of patients with acromegaly, which is usually caused by a growth hormone-secreting pituitary adenoma.¹⁷ In this condition, elevated circulating levels of growth hormone (GH) antagonize insulin action. Circulating concentrations of insulin-like growth factor 1 (IGF-1) are also increased. Although IGF-1 has hypoglycemic properties, its interactions with the insulin and IGF-1 receptors appear to be overwhelmed by the counterregulatory effects of GH. Cushing's syndrome often presents with hyperglycemia, although this condition is notoriously difficult to diagnose until hypercortisolemia leads to other clinical features, such as moon facies, central obesity, hirsutism, hypertension, abdominal striae, emotional lability, and myopathy. Glucocorticoids also antagonize insulin action and augment hepatic gluconeogenesis. Glucose intolerance has been demonstrated in over 80% of patients with Cushing's syndrome.¹⁸ Catecholamines increase hepatic glucose production, decrease and inhibit insulin release. Thus, diabetes can also occur in

patients with pheochromocytoma and/or paraganglioma, with up to two-thirds having some degree of glucose intolerance.¹⁹ Diabetes may also occasionally be encountered in patients with hyperthyroidism, presumably due to augmentation of β -adrenergic activity, and primary hyperaldosteronism, possibly related to decreased insulin release from hypokalemia. Finally, several neuroendocrine tumors of the pancreas are also associated with diabetes, including those elaborating primarily glucagon, vasoactive intestinal peptide, and somatostatin. Glucagonoma is rare, but carries the strongest association with diabetes. This tumor is associated with normocytic anemia and a pathognomonic rash involving the groin, genital, and perineal regions, known as necrolytic migratory erythema.²⁰

Drug- and Chemical-Induced Diabetes

A number of medications have been implicated in the development of diabetes. In most situations, the use of the drug may simply unmask an underlying tendency toward glucose intolerance.²¹ Such drugs include those that contribute to insulin resistance, most notably glucocorticoids, but also growth hormone, levothyroxine (in excess), and niacin.^{4,5} Atypical antipsychotics, especially clozapine and olanzapine, are associated with diabetes, at times manifested by severe hyperglycemia or even ketoacidosis.²² These drugs frequently lead to weight gain but also may directly alter insulin sensitivity. Other diabetogenic medications or chemical agents decrease insulin secretion (β -adrenergic antagonists; calcium channel antagonists; diuretics, especially thiazides; diazoxide; dilantin; and octreotide) or lead to β -cell destruction (pentamidine and the rodenticide, vacor).^{4,5} Certain chemotherapeutic agents or immunomodulators, such as mithramycin, L-asparaginase, and α -interferon, have also been associated with new cases of diabetes, although the precise mechanisms involved are not completely understood.

Infections

Certain viral agents have been implicated as the “environmental” factor that triggers the immune response in T1DM, including rubella, CMV, Coxsackie, mumps, and adenovirus. No specific virus appears to be responsible, however, for most cases.

Uncommon Forms of Immune-Mediated Diabetes

Rarely, patients may present with hyperglycemia and/or hypoglycemia due to anti-insulin or anti-insulin receptor antibodies. Stiff-man syndrome is an autoimmune neurologic affliction associated with increased circulating titers of anti-GAD antibodies and diabetes.

Other Genetic Syndromes

Diabetes or impaired glucose tolerance is also found with increased frequency in a number of congenital disorders such as Down's syndrome, Turner's syndrome, myotonic dystrophy, Klinefelter's syndrome, Prader-Willi syndrome, Huntington's chorea, Wolfram's syndrome, Werner's syndrome, Alstrom's syndrome, Friedrich's ataxia, porphyria, and the Laurence-Moon-Biedl syndrome.^{4,5} In most cases, the diabetes is non-insulin requiring.

Gestational Diabetes Mellitus

Diabetes diagnosed during pregnancy is referred to as gestational diabetes mellitus (GDM), a category that necessarily includes both diabetes first appearing or first being recognized during pregnancy. The diagnosis of GDM is usually made on the basis of a

routine oral glucose tolerance test (OGTT) during the late second trimester. It occurs in approximately 2–5% of all pregnancies, with a greater frequency in those populations with a higher incidence for T2DM, such as Native, African- and Hispanic Americans. Treatment usually consists of diet and exercise, although a minority will require insulin. GDM is accompanied by significant risks to both mother and fetus, such as pregnancy-induced hypertension and fetal macrosomia (with resultant increased frequency of obstetric complications and rates of cesarean delivery). Neonatal complications related to fetal hyperinsulinism (hypoglycemia, hypocalcemia, hypomagnesemia, polycythemia, and hyperbilirubinemia) are associated with increased perinatal mortality.²³ The woman with GDM is at high risk for recurrence of hyperglycemia during future pregnancies and for T2DM later in life.²⁴ Offspring of diabetic pregnancies are themselves at future risk for both T2DM and obesity as adults.²⁵ GDM and T2DM can be considered two variations of the same general disease process, with insulin resistance and obesity (r 25), decrease playing prominent roles in their pathogeneses.

DIAGNOSTIC CRITERIA AND THE SPECTRUM OF ABNORMALITIES IN GLUCOSE HOMEOSTASIS

Diabetes is characterized by progressive elevations in circulating glucose concentrations. In T2DM, these elevations occur over years to decades. As they pass from the normal into the diabetic range, glucose levels transition through an intermediate and less well-categorized phase referred to as impaired glucose tolerance (IGT). While the hyperglycemia of diabetes is clearly associated with an increased risk of microvascular and macrovascular complications, as well as increased mortality, there has been less agreement on the implications of these earlier and more mild glucose elevations. Over the past decade, however, the risk associated with IGT has become clear, with affected individuals at increased risk not only for progression to diabetes, but also for increased cardiovascular morbidity.²⁶ IGT, widely recognized to occur in patients destined to develop T2DM, may be seen in individuals prior to the development of T1DM. In the Diabetes Prevention Trial, for example, a group of asymptomatic subjects at risk for T1DM (on the basis of family history and positive islet cell antibody titers and/or abnormal first-phase insulin secretion during an intravenous glucose tolerance test) demonstrated mild elevations of glucose either while fasting or after an oral glucose challenge.²⁷

Historical Overview

The modern era of diabetes classification began less than 40 years ago, with the first attempt to not only categorize the various clinical presentations of the disease but also to devise acceptable criteria for its diagnosis. Several revisions of this initial schema have since been undertaken by various international bodies, as knowledge has grown in both epidemiologic and pathophysiologic spheres.

First Report of the WHO Expert Committee on Diabetes Mellitus, 1965

The first attempt to “review the current knowledge on diabetes mellitus and to recommend definitions of the various terms used in application to this disorder in the interests of international unifor-

mity” was performed in 1965 by the WHO.¹ In the manuscript that resulted, patients were divided into several categories:

- *Potential diabetic*: An individual with a normal response to a glucose tolerance test (GTT), but who remains at high risk for the future development of diabetes (because of a strong family history or because of having delivered a macrosomic child).
- *Latent diabetic*: An individual with normal response to a GTT, but in whom a GTT in the past had been abnormal, or an abnormal response to a provocative test, such as a cortisone-stimulated GTT.
- *Asymptomatic (subclinical, chemical) diabetic*: An individual with a diabetic response to a GTT but whose fasting venous whole blood glucose is under 125 mg/dL.
- *Clinical diabetic*: An individual with an abnormal GTT response and with symptoms or complications of the disease.

The Committee endorsed the use of some form of oral glucose challenge for the diagnosis of diabetes, although it was not prepared to specify whether the amount of carbohydrate load should be 50 or 100 g. It regarded a normal response 2 hours after a load to be a whole blood venous glucose <110 mg/dL; diabetes was diagnosed if this value reached or exceeded 130 mg/dL. A so-called “borderline state” included those subjects between 110 and 129 mg/dL. While the Committee recognized that the presence of glycosuria with a fasting whole blood glucose of >130 mg/dL likely represented diabetes, their absence in no way ruled out the diagnosis. Each of these parameters was somewhat arbitrary.

Once the diagnosis of diabetes was made, the Committee provided the following recommendations for classifying the various types of this disorder, based solely on age of the patient at the time of disease onset:

- *Infantile or childhood diabetic*: Onset between 0 and 14 years, usually presenting with severe initial symptoms, becoming rapidly insulin-dependent.
- *Young diabetic*: Onset between 15 and 24 years, usually with acute onset of symptoms, with most becoming insulin-dependent.
- *Adult diabetic*: Onset between 25 and 64 years, beginning with variable symptomatology and variable requirements for insulin.
- *Elderly diabetic*: Onset after age 65 years, frequently presenting with symptoms of diabetic complications and often controllable without insulin.

In addition to these types, the Committee also recognized other terminologies, such as *juvenile-type diabetes*, *brittle diabetes*, *insulin-resistant diabetes*, *gestational diabetes*, *pancreatic diabetes*, *endocrine diabetes*, and *iatrogenic (drug-induced) diabetes*. It was recommended, however, that such nomenclature, while useful particularly for purposes of research or population reports, not replace the classification based on age of onset. The Committee also recognized that the diagnostic label of “diabetes” was inadequate and that future consideration should be given to a “fuller and more meaningful descriptive classification.”

International Workshop of the National Diabetes Data Group, 1979

The decade following the first WHO Expert Committee Report witnessed a significant growth in the understanding of the etiology

and pathogenesis of diabetes. This prompted several groups to call for revised international nomenclature, diagnostic criteria, and classification. As a response, the National Institutes of Health convened the National Diabetes Data Group (NDDG).² In 1979, the NDDG published a consensus statement, “Classification and Diagnosis of Diabetes Mellitus and Other Categories of Glucose Intolerance.” Their proposals were endorsed by multiple bodies, including the ADA and the WHO.

In addition to standardizing the OGTT to a 75-g glucose load for nonpregnant adults, the salient new proposals by the NDDG included the following:

1. The classification of diabetic patients on the basis of age of onset should be eliminated. Instead, diabetes should be divided into several distinct subclasses:
 - *Insulin-dependent diabetes mellitus (IDDM), or Type 1*, describing patients whose clinical presentation was characterized by abrupt onset of symptoms, insulinopenia, dependence on injected insulin to sustain life, and proneness to ketosis.
 - *Non-insulin-dependent diabetes mellitus (NIDDM), or Type 2*, describing those patients frequently presenting with few or no symptoms, in whom insulin levels were variable, and who were not ketosis-prone, and therefore did not depend on insulin to sustain life. Some patients with NIDDM would require insulin, however, for the correction of symptomatic fasting hyperglycemia in the setting of failure of the more conventional therapy, oral agents. Patients in this subclass were further divided into obese NIDDM and nonobese NIDDM.
 - *Diabetes associated with other conditions and syndromes*
 - *Gestational diabetes mellitus*
2. Terminologies previously used, such as “chemical,” “latent,” “borderline,” “subclinical,” and “asymptomatic” diabetes should be abandoned. Instead, individuals with plasma glucose (PG) levels intermediate between those considered normal and those considered diabetic should be categorized as “impaired glucose tolerance (IGT)” (see diagnostic criteria below).
3. Individuals with normal glucose tolerance but who had previously experienced transient hyperglycemia, either spontaneously or because of a recognized stimulus, should be categorized as “*previous abnormality of glucose tolerance*.”
4. Individuals at significantly higher risk to develop diabetes than the general population, usually due to a strong family or obstetric history, should be categorized as “*potential abnormality of glucose tolerance*.”
5. The diagnosis of diabetes (in nonpregnant adults) should be restricted to:
 - Those with classical symptoms of diabetes (polyuria, polydipsia, ketonuria, weight loss) and “gross or unequivocal” hyperglycemia.
 - Those with fasting venous PG (FPG) $\geq$ 140 mg/dL on more than one occasion.
 - Those who, if FPG < 140 mg/dL, exhibit sustained elevation of PG during a 2-hour OGTT (described as a PG $\geq$ 200 mg/dL both at 2-hours and at one or more points between 0 and 2 hours).

The NDDG defined normal fasting venous plasma glucose (FPG) as < 115 mg/dL. No category was yet created for those with intermediate FPGs (i.e., 115–139 mg/dL), although the Group did remark that fasting values in this range probably indicated a degree

of abnormal glucose tolerance, the implications of which had not yet been fully assessed.

The cutpoints of 140 mg/dL for FPG and 200 mg/dL for 2-hour PG were demarcated for several reasons: (1) These thresholds were found to be the approximate midpoint separating the two components of the bimodal distribution of FPG and 2-hour PG, respectively, in certain population studies, such as Pima Indians; (2) the prevalence of diabetic microvascular complications, as evidenced by epidemiologic data available at the time, appeared to increase sharply beyond an FPG of 140 mg/dL and 2-hour PG of 200 mg/dL; and (3) a large amount of epidemiologic data had already accumulated based upon these thresholds. The new category of IGT was endorsed in order to identify individuals with plasma glucose responses to oral glucose challenge somewhere between normal and diabetic. It was felt that categorizing these persons as "diabetics" was not justified since they appeared to not carry a risk for developing microvascular complications associated with diabetes, they did not reliably progress to frank diabetes, and they often reverted to normal glucose tolerance upon retesting. Thus, the NDDG criteria were more comprehensive and descriptive, although perhaps less stringent than those of the WHO Expert Committee in 1965.

Second Report of the WHO Expert Committee on Diabetes Mellitus, 1980

The WHO adopted the classification and diagnostic criteria of the NDDG in 1980,³ changing solely the requirements of the OGTT to include only a baseline and 2-hour PG specimen. As a result, IGT could be diagnosed if the 2-hour PG fell between 140 and 199 mg/dL, with the second value ≥ 200 mg/dL at 30, 60, or 90 minutes no longer being required. There was continued emphasis by the WHO on the response to oral glucose as a key element in the diagnosis of diabetes.

The WHO Study Group on Diabetes Mellitus, 1985

In 1985, the only changes made to the previous WHO classification and criteria were very minor.²⁸ The first was the inclusion of "malnutrition-related diabetes mellitus," which was thought to be an important cause of diabetes in tropical developing countries, and included fibrocalculous pancreatic diabetes, as well as protein-deficient pancreatic diabetes. The second was the rounding of SI units for PG values to the nearest tenth of a millimole, instead of to the nearest millimole. Diagnostic criteria were otherwise maintained, with continued emphasis of the plasma glucose response to OGTT.

Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus, 1997

Until 1997, the ADA had endorsed the criteria of the NDDG. In 1995, an international expert committee was invited by the ADA to review the scientific literature since 1979 and to decide if changes to the classification of and diagnostic criteria for diabetes were required.⁴ The Committee published its findings in 1997, and these continue to be endorsed by the ADA. The most notable changes recommended by the Committee include the following:

1. The terms "insulin-dependent" and "non-insulin-dependent," as applied to diabetes, should be abandoned, as they were felt to be both confusing and imprecise. Instead, the main sub-classes of diabetes would be, simply, "type 1" and "type 2."

TABLE 18-2. Diabetes Mellitus: 1997 ADA Diagnostic Criteria*

1. Symptoms of diabetes plus casual plasma glucose concentration ≥ 200 mg/dL (11.1 mmol/L). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.
- or
2. FPG ≥ 126 mg/dL (7.0 mmol/L). Fasting is defined as no caloric intake for at least 8 hours.
- or
3. A 2-hour PG ≥ 200 mg/dL (11.1 mmol/L) during an OGTT. The test should be performed as described by WHO,²⁸ using a glucose load containing the equivalent of 75g of anhydrous glucose dissolved in water.

*In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The third measure (OGTT) is not recommended for routine clinical use.

Source: Reprinted with permission from American Diabetes Association.³²

2. The FPG threshold for the diagnosis of diabetes should be lowered from 140 to 126 mg/dL (Table 18-2).
3. Normal FPG should be < 110 mg/dL; those individuals with FPGs between 110 and 125 mg/dL should be newly categorized as "impaired fasting glucose (IFG)," intended to be the fasting equivalent of IGT.
4. Although the older criteria, using both random (now called "casual") and post-OGTT glucose concentrations, were not changed, FPG was recommended as the preferred screening and diagnostic test due to its wide availability, simplicity, and convenience over OGTT. (See Table 18-3 for the ADA recommended screening guidelines.)

This decision to reduce the diagnostic threshold for FPG was based on epidemiologic data that emerged since the NDDG criteria were developed. It was recognized that only one in four individuals without a prior diagnosis of diabetes but with a 2-hour PG ≥ 200 mg/dL during OGTT also had an FPG ≥ 140 mg/dL.²⁹ Thus, the two cutpoints endorsed by the NDDG and WHO did not actually identify equivalent groups of patients. The Committee also had a practical concern. Many individuals who would have a 2-hour PG ≥ 200 mg/dL during an OGTT would not necessarily

TABLE 18-3. Criteria for Testing for Diabetes in Asymptomatic, Undiagnosed Individuals

Testing for diabetes should be considered in all individuals at age 45 years and above and, if normal, it should be repeated at 3-year intervals.

Testing should be considered at a younger age or be carried out more frequently in individuals who:

- Are obese ($\geq 120\%$ desirable body weight or a BMI ≥ 27 kg/m²).
- Have a first-degree relative with diabetes.
- Are members of a high-risk ethnic population (e.g., African-American, Hispanic American, Native American, Asian American, Pacific Islander).
- Have delivered a baby weighing > 9 lb or have been diagnosed with GDM and are hypertensive ($\geq 140/90$).
- Have an HDL cholesterol level ≤ 35 mg/dL (0.90 mmol/L) and/or a triglyceride level ≥ 250 mg/dL (2.82 mmol/L).
- On previous testing, had IGT or IFG.

undergo such testing, either because they were asymptomatic or because the diagnosis of diabetes had already been confirmed on the basis of an FPG ≥ 140 mg/dL. Since the OGTT identifies more individuals with diabetes than does the FPG, routine use of the OGTT would be necessary for optimal case finding. Yet, in routine practice, the more expensive and inconvenient OGTT was rarely performed. Several studies had also shown that the actual FPG level equivalent to the 2-hour PG cutpoint of 200 mg/dL ranged between 120 and 126 mg/dL. In addition, and perhaps more importantly, the Committee reviewed three studies relating plasma glucose levels to the prevalence of retinopathy, one in Pima Indians,³⁰ a second in Egyptians,³¹ and a third involving participants in the Third National Health and Nutrition Examination Survey (NHANES III).³² In each of these, the FPG threshold distinguishing those subjects at increased risk for microvascular disease was observed at approximately 120–130 mg/dL (with the 2-hour PG threshold remaining at approximately 200 mg/dL) (Fig. 18-1). Thus, the Committee felt that it was mandatory that the fasting diagnostic criteria for diabetes be revised so that the discrepancy in diagnostic power between the FPG and 2-hour PG would be diminished and in order to facilitate and encourage the use of a simpler test, namely FPG. The cutpoint of 126 mg/dL was chosen.

On the basis of epidemiologic estimates, the Committee expected only slightly fewer individuals would be identified as having diabetes using the new FPG criteria, as compared to the WHO cutpoints using both FPG and 2-hour PG. In the Cardiovascular Health Study, however, Wahl and coworkers reported a significant difference in the prevalence of diabetes as identified by these two sets of criteria. The prevalence of untreated diabetes was found to be 14.8% using the WHO criteria and only 7.7% using the new ADA fasting criteria.³³ Similar conclusions were made by Gabir and colleagues in Pima Indians³⁴ and Resnick and colleagues, using NHANES III data.³⁵

Overall, however, in clinical practice, because of low utilization of OGTTs, the change in the ADA criteria has effectively led to an increase in the number of patients identified as having diabetes. It has been estimated, for example, that the change has resulted in the diagnosis of patients an average of 7 years earlier as compared to the older fasting criteria.³⁶

WHO Consultation on the Diagnosis and Classification of Diabetes Mellitus, 1999

In keeping with the new criteria of the ADA, the WHO in 1999³⁷ similarly reduced their cutpoint for venous FPG to 126 mg/dL and affirmed the new category of IFG (impaired fasting glycemia) for those with FPGs between 110 and 125 mg/dL (Table 18-4). If an OGTT had been performed, however, and if the 2-hour PG reached or exceeded 140 mg/dL, the IGT diagnosis would predominate. The diagnostic glucose ranges for IGT were not changed from the WHO 1985 report, and remained identical to those accepted by the ADA. In contrast to the ADA criteria, however, the WHO continued to recommend use of the OGTT for purposes of clinical research. For clinical practice, unless the FPG was already in the diabetic range, the WHO also recommended an OGTT if a random glucose level was in the "uncertain" range [i.e., between the levels that "establish" (200 mg/dL) or "exclude" (100 mg/dL) diabetes (Fig. 18-2.)] It was also emphasized that IGT and IFG were not diagnostic classes by themselves, but instead stages in the natural history of abnormal carbohydrate metabolism (Fig. 18-3).

FIGURE 18-1.

TABLE 18-4. Diabetes Mellitus: 1999 WHO Diagnostic Criteria

	Venous Plasma Glucose (mg/dL (mmol/L))
Diabetes mellitus	
Fasting	≥ 126 (≥ 7.0)
or	
2-hour postglucose load	≥ 200 (11.1)
or both	
Impaired glucose tolerance (IGT)	
Fasting (if measured)	< 126 (< 7.0)
and	
2-hour postglucose load	140–199 (7.8–11.0)
Impaired fasting glycemia (IFG)	
Fasting (if measured)	110–125 (6.1–6.9)
and	
2-hour postglucose load (if measured)	< 140 (< 7.8)

Comparison of Current ADA and WHO Criteria

Since the release of the 1997 ADA diagnostic criteria, several studies have compared their performance with those of the WHO. Gabir and colleagues compared the ADA and WHO criteria and their relation to the development of microvascular complications, finding no difference in their predictive value.³⁸ Others have also affirmed that, although OGTT-driven diagnostic algorithm will find more individuals with diabetes, the current ADA fasting criteria are adequate to identify those persons at risk for microvascular disease resulting from their hyperglycemia.³⁹

The DECODE Study Group evaluated the impact of using FPG versus OGTT criteria on the identification of individuals at risk for macrovascular disease. Existing baseline data on glucose concentrations in the fasting state and 2 hours after a 75-g glucose load from 10 prospective European cohort studies including more than 15,000 men and 7000 women were analyzed. Hazard ratios for all-cause mortality and cardiovascular disease end-points were estimated. The investigators concluded that use of 2-hour PG enhanced the predictive value of FPG alone, whereas the converse was not true. Therefore, while both FPG and 2-hour PG appear to perform equivalently in the identification of microvascular risk, FPG alone may fail to sufficiently identify those at increased macrovascular risk, and the 2-hour glucose during an OGTT may provide additional prognostic information.⁴⁰ Barzilay and coworkers performed a similar analysis on a separate data set. Not unexpectedly, there was a higher prevalence of cardiovascular disease among individuals with IGT or newly diagnosed diabetes by both ADA and WHO criteria than among those with normal glucose levels. However, since fewer subjects were classified as abnormal by the fasting ADA criteria than by the WHO criteria, the number of cases of cardiovascular disease attributable to abnormal glucose status by ADA criteria was one-third of that attributable by WHO criteria. Con-

versely, those classified as normal by the ADA fasting criteria had more cardiovascular events during the follow-up period than did those deemed normal by the WHO criteria. The investigator concluded that the current fasting ADA criteria were less predictive than those of the WHO for the burden of cardiovascular disease associated with abnormal glucose metabolism in the elderly.⁴¹ Saydah and colleagues have shown similar trends using NHANES II data.⁴²

Comparison of Two Stages of Abnormal Glucose Homeostasis: IGT and IFG

Although IFG was devised to be the fasting equivalent of IGT, studies performed since 1997 demonstrate that these two categories of early abnormal glucose homeostasis are not necessarily interchangeable diagnoses. Based on NHANES III data, for example, 14.9% of Americans between the ages of 40 and 74 have IGT, whereas 8.3% have IFG, and 3.9% carry both diagnoses.⁴³ That is, only a minority of patients with either IFG or IGT meet criteria for the other diagnosis. Moreover, while almost one-quarter of the U.S. population in this age group has either IFG or IGT, less than 1 in 25 has both conditions simultaneously.⁴³

Patients with IFG and those with IGT also appear to have distinct metabolic abnormalities. Investigators studied a large group of Pima Indians using hyperinsulinemic euglycemic clamps, glucose isotope infusions, and intravenous glucose tolerance tests (IVGTTs) to assess insulin sensitivity, insulin secretion, and endogenous glucose production. Subjects with isolated IFG (i.e., IFG, but not IGT) and those with isolated IGT (i.e., IGT, but not IFG) demonstrated equally reduced insulin sensitivity. IFG subjects had worse insulin secretory responses to IVGTTs and increased endogenous glucose production, compared to IGT subjects. Individuals with *both* IFG and IGT had the most severe abnormalities in all metabolic parameters. Thus, Pima Indians with isolated IFG and isolated IGT show similar impairments in insulin action, but those with isolated IFG have a relatively more pronounced defect in early insulin secretion and greater augmentation of endogenous glucose production. The most severe abnormalities are exhibited by those with combined IFG and IGT.⁴⁴ The risk of progressing to T2DM appears to be equivalent between those with isolated IFG and isolated IGT, and those who carry both diagnoses progress at the highest rate.⁴⁵ From the DECODE study, individuals with IGT seem to have the greater risk for developing cardiovascular disease, which may indicate a greater influence on vascular disease from post-prandial hyperglycemia.⁴⁶

COMMON TESTS USED TO EVALUATE GLUCOSE HOMEOSTASIS

Glucose Concentrations

For *fasting glucose* determinations, blood should be obtained in the morning after an overnight fast of at least 8 hours. It has been recently demonstrated that approximately half of patients with FPG ≥ 126 mg/dL in the morning will convert to a nondiabetic FPG if the fast is continued into the afternoon.⁴⁷ Although there is a tendency for a gradual climb in FPG with aging, criteria for normal FPG are not age-adjusted.

A “*random*” or “*casual*” glucose determination is that which is obtained without regard to meal. Generally, and depending on the amount of time since the most recent consumption of calories, random levels are higher than fasting levels. In the acutely ill or infirm,

or those immobilized or at bed rest, random (and even fasting) plasma glucose may be in an abnormal range, only to normalize when the patient has been returned to proper health. While the implications of such abnormalities are not entirely clear, it is important to reserve a permanent decision about a patient’s glucose tolerance until he or she is back to a baseline health and activity level.

Type and Source of Fluid

Venous plasma or *serum* is considered the standard body fluid for the determination of glucose concentration, being representative of the extracellular glucose content. Serum and plasma glucose values are essentially identical. The latter is measured by most laboratories and has been historically used in most clinical research studies. *Whole blood* determinations are typically 15% lower than plasma or serum⁴⁸ and may also be influenced by the hematocrit. Ideally, phlebotomized blood should be collected in test tubes containing sodium fluoride, which will inhibit red blood cell glycolysis. Alternatively, the blood can be chilled immediately, with the plasma or serum expeditiously separated from cellular contents. *Arterial blood* has a glucose content approximately 7% higher than that of venous blood.⁵ In the fasting state, this difference is less than in the postprandial setting. *Capillary blood* glucose is similar to that of arterial blood.

The easy availability of capillary blood is taken advantage of by home glucose meters, which are hand-held monitoring devices that provide the patient the ability to test his or her own blood glucose at any time day. Home glucose monitoring has become an integral part of the management of patients with diabetes.⁴⁹ A large variety of meters are currently on the market, with many different features, including interfaces with computer software, allowing for intricate forms of data analysis. Many of the newer meters automatically adjust their results to be displayed as standardized to plasma glucose. While extremely useful for the monitoring of established patients, personal glucose monitors are neither accurate nor precise enough for diagnostic purposes.

Urine glucose is a poorly sensitive marker of diabetes, since the renal glucose threshold in most individuals is not reached until the extracellular glucose concentration exceeds 180 mg/dL. In addition, the urine glucose result is in part dependent on the dilutional effects of recent fluid intake. Prior to the availability of home capillary blood glucose meters, urine testing was an acceptable means for the rough assessment of glycemic control. Except for unusual circumstances where capillary glucose monitoring is impractical, urine glucose testing is no longer considered appropriate for either diagnostic or monitoring purposes.

Oral Glucose Tolerance Test

The homeostatic mechanisms serving to maintain normal glucose concentrations can be assessed using the physiologic “stress” of providing the patient a rapidly absorbed carbohydrate load: the oral glucose tolerance test (OGTT). As noted previously, more individuals will be diagnosed with various degrees of abnormal glucose homeostasis on the basis of their performance on OGTT than by the simpler measurement of fasting glucose alone. It is currently recommended by the WHO for use when blood glucose levels are otherwise equivocal, in epidemiologic settings to assess for diabetes and impaired glucose tolerance, and during pregnancy to screen for and diagnose gestational diabetes.⁵ Given its relatively cumbersome and time-consuming nature, the ADA recommends that, outside of pregnancy, FPG be used as the routine screening

and diagnostic test.⁴ However, there is a recent move to expand utilization of the OGTT to detect earlier forms of abnormal carbohydrate metabolism because of recent attention to postchallenge blood glucose being a better prognosticator of cardiovascular morbidity than FPG.⁴² In clinical practice, the OGTT is also used in the rare patient who presents with microvascular complications suggesting diabetes (i.e., retinopathy, nephropathy, or neuropathy) but in whom initial glucodiagnostic studies show no abnormalities.

In the standard test, 75 g of anhydrous glucose is dissolved in 250–300 mL of water and administered over 5 minutes.⁴⁸ (In children the glucose load should calculate to 1.75 g/kg body weight, up to a maximum of 75 g.) A baseline glucose level is obtained prior to glucose ingestion, and subsequently every 30 minutes for 2 hours. (The WHO standard is for blood to be obtained fasting and then again only at 2 hours.) Variations of the standard OGTT include the 1-hour test using 50 g glucose for GDM screening and the 3-hour 100-g glucose test for formal testing for GDM.⁵⁰ The 5-hour OGTT has recently fallen out of favor, having been used in the past for the evaluation of reactive hypoglycemia. The concurrent measurement of plasma insulin concentrations (as a surrogate marker of insulin sensitivity) is used occasionally for the inferential diagnosis of insulin resistance.⁵¹

Technical Aspects

As in all assessments of glucose metabolism, great care should be taken to ensure that there is no intervening acute illness that might affect the results of the OGTT. The test should be performed in patients who are not bedridden or physically immobilized. In that situation, the test should be postponed until the patient is back to his or her baseline level of activity and health. A variety of host variables that may alter the results of the OGTT have also been identified. Carbohydrate restriction in the days preceding the test may impair insulin secretion to an extent that may render a test abnormal. It is recommended that the daily diet during the 3 days prior to the test contain at least 150 g of carbohydrates. The test should be performed in the morning after an overnight fast of 8–14 hours' duration. Although the patient is allowed to ambulate to the location of the test, he or she should remain seated during the procedure itself. No calories or fluid should be consumed during the test and the patient should refrain from smoking. As with fasting glucose, aging is associated with diminished glucose tolerance, although the diagnostic criteria are the same for all ages.

Glycosylated Hemoglobin, Hemoglobin A_{1c} (HbA_{1c})

Due to wide fluctuations in circulating glucose concentrations in patients with diabetes, random glucose measurements are often not reflective of overall glycemic control. Even fasting determinations, which tend to be more stable, do not provide a complete picture. Like many proteins, erythrocyte hemoglobin is nonezymatically glycosylated at amine residues in the presence of glucose, which passes freely across red blood cell membranes. The percentage of hemoglobin molecules undergoing this reaction is proportional to the average ambient glucose concentrations during the preceding 60–90 days. "Glycohemoglobin" and "hemoglobin A_{1c} (HbA_{1c})" are, therefore, commonly used laboratory tests for assessing long-term diabetic control. HbA_{1c}, with a normal range of approximately 4–6% in most laboratories, refers to the percentage of hemoglobin molecules with glucose moieties attached to N-terminal valines of each of the two β -chains.⁴⁷ Glycohemoglobin (normal range, ap-

proximately 6–8 %) includes HbA_{1c}, but also other forms of hemoglobin where glycosylation has occurred at other amino acids.⁴⁷ HbA_{1c} is more popular and is primarily used in the ongoing follow-up of diabetic patients. A highly specific test for diabetes, HbA_{1c} is not sensitive enough to be used for screening purposes.⁵² That is, patients with mild hyperglycemia, clearly within the diabetic range by FPG or 2-hour PG, may have HbA_{1c} in the high-normal range. This is particularly the case since the lower diagnostic criteria of the ADA have been used. For instance, in one analysis of two large data sets including NHANES III, 87% of individuals with IFG and 61% of those with FPGs in the diabetic range had normal HbA_{1c}. In contrast, when the older criteria, FPG $\geq$ 140 mg/dL, were used, only 19% of diabetic patients had normal HbA_{1c}.⁵³ Hemoglobinopathies and states of rapid red cell turnover may make glycohemoglobin and HbA_{1c} values difficult to interpret.

Emerging Technologies

Interstitial sensors are currently available for use in diabetic patients for continuous monitoring of extracellular glucose concentrations. Interstitial glucose approximates plasma glucose, particularly when determining glycemic trends. A current commercially available model is used for a 72-hour period, with the interstitial probe inserted subcutaneously and attached to a computerized unit that can be worn on the belt.⁵⁴ The readings are downloaded at the end of the recording period for computerized analysis at the practitioner's office. Several companies are actively pursuing refined versions of sensors that can provide a live display to the patient. Fully implantable sensors are also under investigation, as are units that can communicate directly with insulin delivery pumps to comprise an "artificial pancreas." Recently, a wristwatch-like sensor device was approved by the U.S. Food and Drug Administration (FDA).⁵⁵ This unit uses a process known as reverse iontophoresis (applying a gentle electrical current to the skin to express minute amounts of interstitial fluid, which can be analyzed for glucose content) and can measure glucose levels every 20 minutes. The results are provided to the patient on the device's display. Twice-daily calibration with the readings from routine capillary blood glucose monitoring is still required. Others have proposed the direct measure of the glucose content in tears or its indirect measurement, either transcutaneously or through the anterior chamber of the eye using laser technology. At the time of this writing, these and other emerging technologies appear promising for glucose monitoring in diabetic patients, although they will most likely lack the necessary precision for diagnostic purposes. However, if sufficiently sensitive, they may have a role for population screening.

William C. Knowler

TYPE 1 DIABETES MELLITUS (T1DM)

According to the current classification of diabetes mellitus,^{1,2} type 1 diabetes (T1DM; previously called insulin-dependent or juvenile diabetes) is caused by β -cell destruction, often immune-mediated, that leads to loss of insulin secretion and absolute insulin deficiency. Type 1a (autoimmune form) diabetes (T1aDM) is preceded by a subclinical period of T-cell-mediated autoimmune destruction of β cells, marked by the presence of autoantibodies of variable duration.³ This is the most common form of diabetes among children and adolescents of European origin. In children, the disease is usually characterized by a rapid onset with acute symptoms and dependence on exogenous insulin for survival. T1aDM is nearly as frequent in adults, but often, less dramatic onset may lead to misclassification as Type 2 (T2DM) and a delayed insulin treatment. In most patients, the etiology of the autoimmune process and β -cell destruction is not known. T1DM also includes cases that are thought not to be immune-mediated, but are characterized by absolute insulin deficiency (T1bDM) (see Chap. 18).⁴

T1DM accounts for 5–10% of all diagnosed diabetes. About 40% of persons with T1DM are younger than 20 years of age at onset, thus making diabetes one of the most common severe chronic diseases of childhood, affecting 0.3% of the general population by the age of 20 years and 0.5–1% during the life span.⁵ The incidence of the disease appears to be increasing by 3–5% per year.^{6–8} It is estimated that approximately 1.4 million in the United States, and perhaps 10–20 million people globally suffer from the disease.^{9,10} The high incidence, associated severe morbidity, mortality (see chapters on complications and mortality), and enormous health care expenditures^{11,12} make T1DM a prime target for prevention.

NATURAL HISTORY OF TYPE 1a DIABETES

The natural history of T1aDM (Fig. 19-1) includes four distinct stages that can be observed in a vast majority of the patients: (1) preclinical β -cell autoimmunity with progressive defect of insulin secretion, (2) onset of clinical diabetes, (3) transient remission, and (4) established diabetes associated with acute and chronic complications and premature death. At each stage, a spectrum of clinical manifestations and laboratory measurements helps to define the etiology, severity, prognosis, and prevention goals (Table 19-1).

PRECLINICAL β -CELL AUTOIMMUNITY

T1aDM results from a chronic autoimmune destruction of the pancreatic islet β cells, probably initiated by exposure of a genetically susceptible host to an environmental agent. While the candidate genetic and environmental factors appear to be quite prevalent, β -cell autoimmunity develops in less than 5% and progresses to diabetes in less than 1% of the general population.

The autoimmune process is mediated by macrophages and T lymphocytes with circulating autoantibodies to various β -cell antigens (see Chap. 20). Epidemiologic studies have defined autoimmunity as the presence of autoantibodies,³ because in contrast to the cellular markers, their measurement is reliable and standardized across laboratories. Earlier studies have described the epidemiology of β -cell autoimmunity by measuring islet cell antibodies (ICAs) in the classical immunofluorescence test using pancreatic tissue.¹³ This test has been notoriously difficult to standardize and has been replaced by a combination of assays for antibodies against specific β -cell antigens, such as insulin (IAA)^{14–16} glutamic acid decarboxylase (GAD),^{17,18} or ICA512 (IA-2).¹⁹ These tests are quite sensitive and predictive in relatives of T1DM patients^{20,21} and in the general population.²²

Prevalence and Incidence

The prevalence data on β -cell autoimmunity in school children from various countries²³ are summarized in Fig. 19-2 and compared with the incidence of T1DM in these countries. The prevalence of ICAs varied from 0.2% in Dutch to 4.4% in Sardinians; however, the rates are not strictly comparable, because of different ICA assays and cut-off values for positivity as well as different age groups screened. The prevalence of β -cell autoimmunity appears to be roughly proportional to the incidence of T1DM in the populations.²⁴ In contrast, the prevalence of β -cell autoimmunity in first-degree relatives of T1DM persons does not differ as dramatically between high and low T1DM risk countries (Fig. 19-3).

No reliable estimates of the incidence of β -cell autoimmunity in the general population have been published, but appropriate cohort studies are underway in the United States²⁵ and Finland.²⁶ In siblings of Finnish T1DM children, the incidence of combined β -cell autoimmunity or T1DM was up to 1.4% per year.²⁷ In New Zealand, the incidence was 3.7% per year in relatives younger

FIGURE 19-1. Natural history of type 1 diabetes.

than 5, compared to 0.5% per year in those 5–9 years old. None of the 356 relatives older than 10 years converted over a period of 5 years.²⁸ This suggests that relatively few children develop β -cell autoimmunity after the age of 5 and some may recover from autoimmunity.^{29,30}

Little data concerning β -cell autoimmunity are available for non-Caucasian populations. Compared with Caucasians, first-degree relatives of African-American T1DM probands had somewhat higher prevalence of ICAs,³¹ but at T1DM onset, the proportions were reversed.³² Among 86,000 relatives of T1DM patients screened for the DPT-1 trial, lower prevalence of ICAs was observed in Asian Americans (2.6%) and in Hispanics (2.7%), compared to African-Americans (3.3%) or non-Hispanic whites (3.9%) (Skyler, unpublished data, 2001). Lower prevalence of GAD antibodies in Asian compared to Caucasian type 1 diabetes patients has also been reported.³³

No significant gender difference in the prevalence of β -cell autoimmunity, either in first-degree relatives or in the general population, has been published. However, the crude DPT-1 screening data (not adjusted for age, relation to proband or ethnicity) have

suggested higher prevalence of ICAs in males (4.3%) than in females (3.3%). No reliable information is available concerning potential seasonal or annual variation in the incidence of β -cell autoimmunity. Preliminary reports from Finland (Simell, unpublished data, 2001) suggested that the seasonality of autoantibody appearance may mimic that of the clinical onset, indirectly implying that similar infections may trigger autoimmunity and progression to diabetes.

Genetic Factors

Family History

The prevalence of β -cell autoimmunity in first-degree relatives of type 1 diabetic persons is increased 3–5 times, compared to that in school children with no family history of T1DM. This is less than expected, knowing that the risk of T1DM among the relatives is 20 times higher than that in the general population.

Candidate Genes

In contrast to the wealth of data concerning genetic markers associated with clinical diabetes, little is known about the genetic determinants of β -cell autoimmunity. No particular HLA type seems to be associated with β -cell autoimmunity, although inconsistent associations between insulin or GAD autoantibodies and HLA-DR,DQ phenotypes have been reported. The HLA-DR2, DQB1*0602 haplotype, which almost completely protects from T1DM,³⁴ is found in about 15% of GAD- and IAA-positive young relatives of T1DM patients.^{35–37} However, over 90% of those strongly and/or persistently ICA-positive are HLA-DR3 or 4, similar to T1DM patients.³⁸ Children with β -cell autoimmunity identified from the general population also show a variety of HLA genotypes, but 90% of those persistently ICA-positive are DRB1*04, DQB1*0302.^{39,40} This may suggest that HLA genes are not involved in the initiation of β -cell autoimmunity, but rather deter-

TABLE 19-1. Natural History of Type 1 Diabetes

	Preclinical Autoimmunity	Clinical Onset	Remission	Long-Standing Diabetes
Clinical	—	Polyuria, polydipsia Weight loss DKA in 20–40% Insulin dependence	Insulin independence partial in 20–70% Total in 10–30%	Acute complications: DKA, hypoglycemia, infections Chronic complications: retinopathy, nephropathy, neuropathy, hypertension, atherosclerosis, growth impairment Premature mortality
Laboratory

Tertiary	—	Of onset mortality	Of acute complications	Of complications, mortality

FIGURE 19-2. Geographic differences in the prevalence of islet cell antibodies (ICA) in school children, compared with the incidence of type 1 diabetes (ages 0–14 years) in the area.

mine progression to diabetes. More subjects with β -cell autoimmunity need to be genotyped to precisely determine the role of HLA and additional T1DM candidate genes^{41–47} in the initiation of autoimmunity and progression to diabetes.

Environmental Factors

Viruses

Viral infections appear to initiate autoimmunity rather than precipitate diabetes in subjects with autoimmunity. Two infections with similar viruses may be needed. Mice persistently expressing a viral protein in the β cells do not develop β -cell autoimmunity unless exposed to the same virus later in life.^{48,49} ICAs or IAAs have been detected after mumps,⁵⁰ rubella, measles, chickenpox,⁵¹ Coxsackie,⁵² ECHO4,⁵³ and rotavirus⁵⁴ infections. Newborns and infants are particularly likely to develop a persistent infection and among patients with congenital rubella syndrome, 70% have ICAs.⁵⁵

The evidence is strongest for picornaviruses, which include human (enteroviruses and rhinoviruses) and animal pathogens (e.g., mouse EMC virus and Theiler's virus). Picornaviruses induce T1DM in numerous animal models, and their tropism to human β cells has been demonstrated.⁵⁶ A molecular mimicry between the P2-C protein of Coxsackie virus and the GAD protein⁵⁷ may be responsible for β -cell autoimmunity. Cross-sectional studies of anti-

FIGURE 19-3. Prevalence of islet cell antibodies (ICA) in first-degree relatives and in school children in various geographic locations.

Coxsackie antibodies in β -cell autoimmunity have been weak and inconclusive⁵⁸ and have been recently replaced by studies based on detection of picornaviral RNA in bodily fluids using PCR. Prospective studies of nondiabetic relatives and general population children found a strong relation between enteroviral infections, defined by PCR, and development of islet autoantibodies in Finland^{59–6} but not in the United States (Graves, unpublished data, 2000).

Dietary Factors

Exposures to cow's milk bovine serum albumin (BSA) or β -casein prior to gut cellular tight junction closure or during gastroenteritis when the intestinal barrier is compromised are alternative causes of β -cell autoimmunity. Cow's milk or wheat introduced at weaning triggers insulinitis and diabetes in animal models,⁶² perhaps through a molecular mimicry.⁶³ Human data are conflicting, but predominantly negative.^{64,65–70}

The association between cow's milk and autoimmunity could be due to the effect of β -casein immunostimulating hexapeptide present in enzymatic hydrolysate of milk from *Bos taurus* cows but not from *Bos indicus* cows.⁷¹ Chemical compounds (streptozocin⁷² or dietary nitrates and nitrozamines⁷³) induce β -cell autoimmunity in animal models. Multiple hits of dietary β -cell toxin may render genetically resistant individuals susceptible to diabetogenic viruses, leading to T1DM.⁷⁴

Gene–Environment Interactions in β -Cell Autoimmunity

Host–Virus Interactions

Both the susceptibility genes and the environmental risk factors for human β -cell autoimmunity are poorly defined. In mice the host's genes restrict the diabetogenic effect of picornaviruses in a manner compatible with a recessive trait not related to the MHC (for review see reference 56). In humans, the HLA-DR3 allele is associated with viral persistence. It remains to be established which additional genetic variants interact with infectious agents to promote β -cell autoimmunity in humans.

Host–Diet Interactions

The postulated autoimmune response to cow's milk proteins is likely determined by the host's age and genetic background. The epidemiologic data are extremely limited and suggest that an early

exposure to cow's milk in relatives with HLA-DR3/4,DQB1*0302,DR3/3 or DRx/4.DQB1*0302 is not associated with the presence of GAAs and/or IAAs at ages 1 to 6 years and may even be protective.⁷⁵ It is unclear whether the effect of HLA-DR3 differs from that of HLA-DR4,DQB1*0302, and whether other T1DM-associated genes are involved.

Primary Prevention of β -Cell Autoimmunity

Prevention of Diabetogenic Viral Infection

In mice, it is possible to prevent encephalomyocarditis virus-induced diabetes by immunization with a nondiabetogenic variant of the virus.⁷⁶ The interactions between HLA, antigen, and T-cell receptor, as well as the genetic determinants of viral diabetogenicity, are being disentangled. It may become possible to design recombinant vaccines that would provide optimal antigenic stimulus in the context of the host's HLA, providing long-term protection against diabetogenic strains and avoiding adverse effects. Approaches alternative to vaccination include antiviral agents.⁷⁷

Dietary Factors

If early exposure to cow's milk triggers β -cell autoimmunity in humans, a logical primary prevention would include avoidance of cow's milk, especially in those with T1DM-associated HLA alleles. Such an intervention has been piloted in newborn relatives of T1DM patients,⁷⁸ and a large multicenter trial is under way. Current data are insufficient to support cow's milk avoidance for prevention of β -cell autoimmunity and type 1 diabetes.

Progression from β -Cell Autoimmunity to Clinical Diabetes

The duration of preclinical β -cell autoimmunity is variable and precedes the diagnosis of diabetes by up to 9–13 years.^{79,80} In most persons with persistent autoantibodies, there is an early loss of spontaneous pulsatile insulin secretion and progressive reduction in the acute insulin response to intravenous glucose load, followed by decreased response to other β -cell secretagogues, impaired oral glucose tolerance, and fasting hyperglycemia.⁸¹ However, a non-progressive β -cell defect can exist for many years in some monozygotic twins and other relatives of T1DM persons.

Studies in first-degree relatives of T1DM patients^{80,82,83} and in school children with no family history of T1DM^{29,30,39,84,85} have reported ICA "remission" rates between 10 and 78%. It is unclear whether such remissions really occur or are an artifact of low specificity of autoantibody assays. If autoimmunity remits at the reported rates, only 1 in 2–8 of autoimmune children will develop diabetes by the age of 20 years. In those who lose their autoantibodies or remain autoimmune but do not progress to diabetes, it is presumed that the penetrance or number of susceptibility genes or the causative environmental exposures are insufficient. It is possible that β -cell autoimmunity remits spontaneously in genetically resistant persons or when the offending factor is removed, similar to celiac disease. Age also plays a role, because children younger than 10 years have a threefold increased risk of progressing from autoimmunity to T1DM, compared to older relatives.³¹

β -cell autoimmunity may remit and reappear in the course of viral infections or variable exposure to causal dietary factors. The cumulative β -cell damage and increases in insulin resistance with obesity and physical inactivity may eventually cause diabetes at a later age. Those persons in whom the disease process is slow may

present with T1DM as adults, develop diabetes that does not immediately require insulin treatment, or may even fail to develop diabetes altogether. Markers of autoimmunity can be detected in 14–33% of diabetes patients classified on clinical grounds as "type 2"^{86,87} and are associated with early failure of oral hypoglycemic drug therapy and insulin dependence in these patients. The term *latent autoimmune diabetes of adults (LADA)*⁸⁸ has been coined for this slowly progressing form of T1DM.

Primary Prevention of T1DM in Persons with β -Cell Autoimmunity

ICA-positive relatives of T1DM patients have become the primary target of clinical trials to prevent T1DM.^{89–91} Some of the proposed interventions are associated with significant adverse effects.^{92–94} The effectiveness of oral nicotinamide⁹⁵ is being tested in the ENDIT study⁹⁶ (results expected in 2002), but smaller studies⁹⁷ have not been promising. Promising results of a pilot trial with parenteral insulin⁹⁸ gave impetus to a large randomized unmasked trial of low-dose SC/IV insulin in relatives with confirmed ICA positivity and low acute insulin response to IV glucose (Diabetes Prevention Trial-1⁹⁹). The results of this trial were announced in 2000, but unfortunately showed no efficacy of insulin injections in preventing or delaying diabetes onset. The oral insulin arm of the DPT-1 is in progress, but results of smaller studies in newly diagnosed patients have not been encouraging.^{100,101} Trials involving induction of tolerance to insulin or GAD using altered peptide ligands are being tested in phase II clinical studies.

CLINICAL ONSET OF T1DM

In industrialized countries, 20–40% of T1DM patients younger than 20 years present in diabetic ketoacidosis (DKA).^{102–105} Younger age, female gender, HLA-DR4 allele,¹⁰⁶ lower socioeconomic status, and lack of family history of diabetes have been associated with more severe presentation. Severe presentation in younger children may result from greater β -cell destruction at diagnosis, an average of 80% of the islets are damaged at diagnosis in children younger than 7 years, 60% in those 7–14 years old, and 40% in those older than 14.¹⁰⁷ Case fatality in industrialized countries ranges between 0.4 and 0.9%,¹⁰⁸ but little is known concerning its predictors.

Both DKA and onset death are largely preventable, because most of the patients have typical symptoms of polyuria, polydipsia, and weight loss 2–4 weeks prior to diagnosis. The diagnosis is straightforward in almost all cases and can be based on the symptoms, random blood glucose over 200 mg/dL, and/or HbA_{1c} higher than 7%.

Traditionally, nearly all children with newly diagnosed T1DM were hospitalized. More recently, an increasing proportion of new-onset children have been managed on an outpatient basis, especially in urban centers with specialized diabetes education and treatment facilities. In Colorado, the proportion of children receiving only outpatient care at diabetes diagnosis increased from 6% in 1978 to 35% in 1988.¹⁰⁹ Hospitalization at onset does not improve short-term outcomes, such as readmission for DKA or severe hypoglycemia.^{102,105} Onset hospitalizations and acute complications have similar biologic (younger age, lower endogenous insulin secretion) and psychosocial (lower socioeconomic status, limited access to health care, dysfunctional family) determinants.

Prevalence and Incidence of T1DM

T1DM is one of the most common chronic childhood illnesses, affecting world-wide an estimated 50,000 new cases annually⁹ and, in Caucasian populations, 1–3 per 1000 children by the age of 20 years.⁵ Prevalence of T1DM, that is, the number of people in the population who have the disease at a given point in time, is determined not only by disease incidence but also by case survival, which may vary markedly in populations. The prevalence of T1DM in the age group 0–15 years ranges from 0.05% to 0.3% in most European and North American populations.²³ Prevalence data are useful in determining the public health impact of T1DM. For example, it is estimated that there are approximately 123,000 persons aged 0–19 years in the United States who currently have T1DM.¹⁰

Incidence is the rate at which new cases of disease appear in the population and is usually expressed as the annual number of new cases per 100,000 persons. Incidence of T1DM varies by geographic location, ethnicity, age, gender, and time period.

Geographic Location

One of the most striking characteristics of T1DM is the large geographic variability in the incidence (Fig. 19-2).^{110–112} Scandinavia and the Mediterranean island of Sardinia have the highest incidence rates in the world. Asian populations have the lowest T1DM incidence rates. A child in Finland is 400 times more likely to develop diabetes than a child in China. The geographic and ethnic variation in T1DM risk may reflect either different pools of susceptibility genes or different prevalence of causative environmental factors or a combination of both.

The clinical picture of the disease is similar in low- and high-risk areas,^{113,114} making it unlikely that the interpopulation differences are due to misclassification of different types of diabetes. Since in many populations, T2DM is either increasing¹¹⁵ or already the predominant form of diabetes in children,¹¹⁶ it has been suggested that islet autoantibodies should be measured at onset for correct diagnosis and treatment.¹¹⁷

Race and Ethnicity

Racial differences in T1DM risk within the same population are striking, although they are not of the same magnitude as the geographic differences (Fig. 19-4). American non-Hispanic whites are about one and a half times as likely to develop T1DM as African-Americans or Hispanics.¹¹⁰ This is similar to the differences reported from Montreal, where children of British descent had about one and a half times the risk of T1DM as children of French descent.¹¹⁸

Age

T1DM incidence peaks at the ages of 2, 4–6, and 10–14 years, perhaps due to alterations in the pattern of infections or increases in insulin resistance. The age distribution of T1DM onset is similar across geographic areas and ethnic groups, as demonstrated by data from Allegheny County, Pennsylvania, and Poland (Fig. 19-5). The incidence decreases in the third decade of life,¹¹⁹ only to increase again in the fifth to seventh decades of life.^{120,121} It is not known whether there are etiologic differences between child- and adult-onset T1DM, but they were not apparent among 3672 adult diabetic participants in the UKPDS. Over 30% of those aged 25–34 were positive for ICA and/or GAD autoantibodies, but the prevalence decreased with age, to less than 10% in those aged 55–65.¹²² The presence of the autoantibodies and age of presentation of dia-

FIGURE 19-4. Incidence of type 1 diabetes in children of different ethnic groups living in the same geographic area.

betes were strongly associated with the presence of the HLA-DRB1*03/DRB1*04-DQB1*0302 genotype.¹²³

Gender

In general, males and females have similar risk of T1DM,¹²⁴ with the pubertal peak of incidence in females preceding that in males by 1–2 years. In lower-risk populations, such as Japanese or U.S. blacks, there is a female preponderance, whereas in high-risk groups, there is a slight male excess.^{5,110,125} T1DM diagnosed in adulthood is associated with male excess.^{126–130} These findings contrast with the striking female preponderance in the NOD mouse model of diabetes.¹³¹

FIGURE 19-5. Age distribution of type 1 diabetes incidence under age 15 years Allegheny County, Pennsylvania and in Wielkopolska, Poland, during 1979–1985. (Adapted from reference¹¹⁴)

Time

There is evidence for marked variations in the incidence of T1DM over time, both seasonally and annually. In the Northern Hemisphere, the incidence declines during the warm summer months; similarly, in the Southern Hemisphere, the seasonal pattern exhibits a decline during the warm months of December and January, implicating a climatic factor (Fig. 19-6).¹³² This seasonal pattern appears to occur only in older children,^{133,134} suggesting that factors triggering diabetes may be related to school attendance. The observed seasonality is not an artifact of health care seeking or access, since the seasonality of symptom onset is similar to that of diagnosis and the patterns differ by HLA-DR type.^{135,136}

Most population-based registries have shown increasing T1DM incidence over time,^{6,137-140} while a few have shown no trend.¹³³ Some of the inconsistencies may be attributed to insufficient observation time. For example, initial data from Sweden and Allegheny County, Pennsylvania, showed no temporal trend, however, extended data collection showed increase incidence in these locations.^{138,141} Most studies have observed periodic outbreaks superimposed on a steady secular increase in incidence. Figure 19-7 displays an example of parallel temporal incidence changes in populations that differ vastly in geographic location and the background risk of T1DM¹¹⁴ (Allegheny County, Pennsylvania, and Wielkopolska, Poland). Standardized comparisons confirmed that a pandemic of T1DM occurred during 1984-1986.⁶ While the increase in T1DM incidence has affected all age groups, several studies reported a particular increase among the youngest children.¹⁴²⁻¹⁴⁶

Genetic models are unable to explain the apparent temporal changes in the incidence.¹⁴⁷ The polio model, where autoimmune diabetes results from delayed exposure to infection that is benign when encountered in early childhood, could explain the recent increase in incidence, but not the shift in diagnosis to earlier ages. An alternative explanation invokes the congenital rubella model.

FIGURE 19-6. Seasonal distribution of onset of type 1 diabetes in the United Kingdom and in Chile. (From reference^{1,12})

FIGURE 19-7. Annual incidence of type 1 diabetes in Allegheny County, Pennsylvania (Δ) and Wielkopolska, Poland, (○) by age group, during 1970-1985. (From reference¹¹⁴)

Briefly, increased hygiene in the Western World has led to a decline in herd immunity to common infections among women of child-bearing age. These women are more likely to develop viremia during pregnancy, resulting in congenital persistent infection of β cells and early-onset T1DM in the offspring. This model could explain

both the increasing incidence of diabetes and the decreasing age of disease onset.¹⁴⁸

Genetic Factors

Family History of T1DM

In moderate T1DM risk areas, such as the United States, the risk of T1DM by the age of 15 years is approximately 1/400. The risk is increased to about 1/40 in offspring of type 1 diabetic fathers and to 1/66 in offspring of type 1 diabetic mothers (Dorman and McCarthy, 1993). The risk to siblings of T1DM probands ranges from 1/12–1/35^{149,150} and is further increased, to 1/4, in HLA-identical siblings. It is estimated that by the age of 60 years, approximately 10% of the relatives develop T1DM.¹⁵¹ Family history of T1DM is a surrogate measure of the combination of T1DM genes and environmental exposures shared by family members.

“Familial” cases represent about 10% of T1DM and do not appear to be etiologically different from “sporadic” cases in HLA gene frequencies, seasonality of onset, prevalence of various ICAs, or IgM against Coxsackie B.¹⁵² Familial cases tend to have lower glycosylated hemoglobin and higher C-peptide levels than sporadic cases, because relatives recognize diabetes symptoms earlier; however, these differences disappear soon after diagnosis.

Candidate Genes

The primary loci of genetic susceptibility to T1DM have been mapped to the HLA-DR and DQ regions^{34,153,154}, and new candidate genes outside the HLA region are being identified^{41–47} (see Chap. 20). While 50% of non-Hispanic whites in the United States have the HLA-DR3 or DR4 allele, at least one of these alleles is present in 95% of patients with T1DM. The estimated risk to HLA-DR3/4 children in the general population ranges from 1/35 to 1/90.⁹ The risk is further increased in those with HLA-DR3/4, DQB1*0302 genotype (about 2.2% of the general population versus 30–40% of T1DM patients). For comparison, about 5% of persons in the general population versus 12% of T1DM patients have a first-degree T1DM relative.

Environmental Factors

Twin¹⁵⁵ and family studies indicate that genetic factors alone cannot explain the etiology of T1DM. Seasonality, increasing incidence, and epidemics of T1DM, as well as numerous ecologic, cross-sectional, and retrospective studies, suggest that certain viruses and components of early childhood diet may cause T1DM.

Viruses

Herpesviruses,^{156,157} mumps,^{50,158} rubella,^{55,159} and retroviruses^{160,161} have been implicated. An increased incidence of T1DM in patients with congenital rubella syndrome (CRS) is particularly interesting. While CRS is responsible for a minute proportion of T1DM and there is little evidence that postnatal rubella exposure to the wild strain⁵¹ or to the MMR vaccine¹⁶² causes T1DM, CRS provides an example of viral persistence leading to T1DM. The incubation period of T1DM in CRS patients is 5–20 years¹⁵⁹ and persistent rubella virus infection of the pancreas has been demonstrated in some cases. While CRS is not associated with particular HLA-DR alleles, the distribution of the HLA-DR3 and 4 alleles among patients with CRS and diabetes resembles that in non-CRS T1DM patients.⁵⁵ Finally, a molecular mimicry has been reported between a rubella virus protein and a 52-kD β -cell autoantigen.¹⁶³

Enteroviruses have been most strongly linked to human T1DM, but convincing proof of causality remains elusive (for review see references 56 and 164). Case and autopsy reports,^{165,166} epidemics of T1DM associated with concurrent epidemics of enteroviruses,^{167,168} and multiple cross-sectional seroepidemiologic studies⁵⁶ have been suggestive, but not entirely convincing. At least 90% of T1DM patients demonstrate a prolonged period of β -cell autoimmunity that is hardly compatible with an acute cytolytic enteroviral infection being a major cause. Enteroviral infection could, however, initiate β -cell autoimmunity through molecular mimicry between CBV P2-C protein and GAD^{56,169} or a persistent β -cell infection with impairment of insulin secretion and expression of self antigens. Alternatively, a combination of acinar cell infection and a limited capacity of β cells to neutralize free radicals released in this process could initiate β -cell autoimmunity. Regulating factors could include age of the host, the metabolic activity of the β cell (with the increased demands of puberty or obesity exacerbating the autoimmune process), the HLA-specific restriction of immune responsiveness, and concomitant infection that might cause some degree of immunosuppression or self-tolerance.

Studies from Finland⁵⁹ and Sweden^{170,171} have suggested that *in utero* enteroviral infections can lead to T1DM in a significant proportion of the cases. Additional perinatal factors^{171–177} and season of birth¹⁷⁸ have been associated with T1DM. In animal models viral infection may protect the host from developing T1DM.^{179–181} Evidence for such a protective effect in humans is speculative, at best.^{182–184}

Routine Childhood Immunization

None of the routine childhood immunizations have been shown to increase the risk of diabetes^{162,184–188} or prediabetic autoimmunity.^{189,190}

Dietary Factors

An ecologic study suggested an association between decrease in breast-feeding and increase in T1DM incidence between 1940 and 1980.¹⁹¹ Subsequent case-control studies have shown a negative,^{192,193} a positive,¹⁹⁴ or no association.^{195–197} Certain studies^{192,198} but not others^{194,196,197} suggested a dose–response relationship between the duration of breastfeeding and protection from T1DM. A meta-analysis found a 50% increase in T1DM risk associated with a breastfeeding duration of less than 3 months, and exposure to breast-milk substitutes prior to 3 months of age.¹⁹⁹ Breastfeeding may be viewed as a surrogate for the delay in the introduction of diabetogenic substances present in formula or early childhood diet. Newly diagnosed T1DM children, compared with age-matched controls, have higher levels of serum antibodies against cow's milk and β -lactoglobulin,²⁰⁰ as well as against BSA.²⁰¹ However, it has been difficult to reproduce some of these reports.⁶² More recent cohort studies failed to find an association between infant diet exposures and β -cell autoimmunity.^{68,70,190} Interestingly, a study in Finland suggested that current cow's milk consumption was more closely linked to prediabetic autoimmunity and diabetes than infant exposure.²⁰² Despite these limitations, a dietary intervention trial to prevent T1DM by a short-term elimination of cow's milk from infant diet (TRIGR) is under way.⁷⁸

Circumstantial evidence suggests a connection between T1DM and consumption of foods and water containing nitrates, nitrites, or nitrosamines.^{203–205} Anecdotal reports have shown that toxic doses of nitrosamine-containing compounds and generation of free radicals can cause diabetes.²⁰⁶

Gene–Environment Interactions

T1DM is likely caused by an interactive effect of genetic and environmental factors within a limited age window. While both the susceptibility genes and the candidate environmental exposures appear to be quite common, the likelihood of these causal components meeting within the susceptibility age window is low.²⁰⁷ To investigate the environmental causes of T1DM, the study subjects have to be screened for known susceptibility gene markers so that gene–environment interactions can be accounted for.

Interaction Between HLA Class II Alleles and Viral Infection

Susceptibility to diabetogenic enteroviruses in humans appears to be genetically restricted by HLA-DR and DQ alleles.⁵⁶ However, the allelic specificity is controversial^{106,208–210} and may depend on the viral type and epidemiology. For instance, in Sweden, DR3 was associated with IgM responses to CB4, while DR4 was associated with IgM responses to CB2, CB3, and CB5.²⁰⁸ Elevated antiviral IgM levels in subjects with a specific HLA phenotype may reflect a greater ability to mount an immune response or a higher susceptibility to infection. This explanation is consistent with no apparent relationship between the presence of enteroviral RNA and HLA phenotypes¹⁸⁹ (Graves, unpublished data, 2001).

Interaction between HLA Class II Alleles and Infant Diet

Very few studies to date have examined a possibility of an interaction between the effects of HLA genes and exposure to cow's milk.^{202,211–215} In one of these studies, controlling for birth order, ethnicity, and family income, exposure to whole cow's milk by 3 months of age was associated with T1DM more strongly in children with high-risk HLA than in those with low-risk HLA.²¹¹

REMISSION (“HONEYMOON PERIOD”)

Shortly after clinical onset, most T1DM patients experience a transient fall in insulin requirement due to an improved β -cell function. Total and partial remissions have been reported in, respectively, 2–12% and 18–62%, respectively, of young T1DM patients.^{105, 212,213} Older age and less severe initial presentation of T1DM^{212,215} and low or absent ICA^{215–217} or IA-2²¹⁸ have been consistently associated with deeper and longer remission. Evidence relating GAD autoantibodies,^{215,218,219} non-Caucasian origin, HLA-DR3 allele, female gender, and family history of T1DM to a less severe presentation, greater frequency of remission, and slower deterioration of insulin secretion is inconclusive. Most studies,^{212,217} but not all,^{213,214} agree that preserved β -cell function is associated with better glycemic control (lower HbA_{1c}) and preserved α -cell glucagon response to hypoglycemia.²²⁰ The prevalence of ICA (but not GAD) decreases from 87% at the time of T1DM diagnosis to 38–62% 2–3 years later,^{216,221} faster in young boys, subjects lacking HLA-DR3 and 4, and those diagnosed between July and December.²²¹

The natural remission is always temporary, ending with a gradual or abrupt increase in exogenous insulin requirements. Destruction of β cells is complete within 3 years of diagnosis in most young children, especially those with the HLA-DR3/4 phenotype.²²² It is much slower and often only partial in older patients,²²³ 15% of whom have still some β -cell function preserved 10 years after diagnosis.²²⁴

Secondary Prevention in New-Onset T1DM Patients

A number of the placebo-controlled randomized trials using azathioprine, cyclosporin A, nicotinamide, prednisone, and other immunosuppressive agents attempted to increase the rate and the duration of T1DM remission. Only cyclosporin A treatment has been shown to be partially effective, inducing total remission in 25–40% of patients and sustaining it for 1 year in 18–24% of newly diagnosed patients, compared to 0–10% in the placebo group.^{146,225} However, the drug is nephrotoxic, of little value in children, and effective for only as long as it is administered,²²⁶ rendering this approach to secondary prevention of T1DM unacceptable. Trials using intensive insulin treatment,^{227,228} oral insulin,²²⁹ or immunomodulation²³⁰ have been even less successful than cyclosporine A trials. Recently completed or ongoing prevention trials are listed in Table 19-2.

ESTABLISHED DIABETES

Complications

Acute complications of T1DM: (diabetic ketoacidosis, hypoglycemia, and infections) are described in detail in Chaps. 31, 34, and 36. The risk of hospital admission for acute complication is 30/100 patient-years in the first year of the disease and 20/100 in the subsequent 3 years.¹⁰⁵ An estimated 26% of the patients have at least one episode of severe hypoglycemia within the initial 4 years of diagnosis, with little relation to demographic or socioeconomic factors. The incidence of severe hypoglycemic episodes varies between 6 and 20/100 patient-years, depending on age, geographic location, and intensity of insulin treatment.¹⁰⁵

Diabetes is the leading cause of end-stage renal disease, blindness, and amputation, and a major cause of cardiovascular disease and premature death in the general population.²³¹ The disease results in over \$5 billion in medical care expenditures per year, with costs for patients over 10 times those for nondiabetics.¹¹ These aspects of diabetes are highlighted in other chapters of this book.

Mortality

Insulin treatment dramatically prolongs survival, but it does not cure diabetes. Although the absolute mortality at onset and within the first 20 years of T1DM is low (3–6%), it is 5 times higher for diabetic males and 12 times higher for diabetic females, compared to the general population.²³² This excess mortality is lowest in Scandinavia, intermediate in the United States, and highest in countries where T1DM is rare, for example, Japan,^{233,234} probably due to a combination of the quality of care and access. Even in Finland, at least a half of the deaths are due to currently preventable causes such as acute complications, infections, and suicide.²³⁵ On the other hand, 40% of the patients survive over 40 years and half of these have no major complications. Survival and avoidance of complications have been related to better metabolic control²³⁶; however, genetic factors also appear to be involved. Inconsistent associations have been reported between diabetic nephropathy and HLA-DR4²³⁷ and several genes involved in blood pressure regulation.^{236,238–244} Polymorphisms of apolipoproteins E and A-IV²⁴⁵ appear to play a role in the development of coronary artery disease in T2DM patients, but have not been extensively studied in persons with T1DM.

TABLE 19-2. Selected Recent or Ongoing Type 1 Diabetes Prevention Trials

Nonantigen Specific	Antigen Specific
<i>Secondary Prevention Trials (in Newly Diagnosed Patients)</i>	
MMF and DZB: P. Gottlieb, Colorado and Seattle	Italy/France ⁹ Oral Insulin: No effect
Anti-CD3 hOKT3 IV: K. Herold, New York; F. Gorus, The Netherlands	Oral Insulin, N. Maclaren: ↑ C-peptide?
HSP 65 p277 (Peptor) SC: D. Elias, Israel	NBI 6024-003, Neurocrine
Multidose DZB: H. Rodriguez, Indiana	hGAD SC in alum, Diamyd
Oral hIFN- α : S. Brod, Texas	
Q fever vaccine SC: K. Lafferty, Australia	
Diazoxide: E. Bjork and A. Karlsson, Sweden	
Lisofylline IV: S. Kirk	
Vitamin E + nicotinamide: P. Pozzilli, Italy	
<i>Primary Prevention Trials (In Nondiabetic Relatives)</i>	
ENDIT: Nicotinamide	Joslin/BDC ⁹ parenteral insulin: Delay
TRIGR: Casein hydrolysate (cow's milk elimination)	Schwabing ⁹ parenteral insulin: Delay
	DPT-1 ⁹ parenteral insulin: No effect
	DPT-1 ⁹ oral insulin: ?
	DIPP ⁹ nasal insulin: ?
	INIT ⁹ IntraNasal Insulin trial: ?

Tertiary Prevention

The Diabetes Control and Complication Trial²⁴⁶ and a number of smaller studies have demonstrated that intensive insulin therapy that maintains blood glucose concentrations close to the normal range can delay the onset and slow the progression of diabetic retinopathy, nephropathy, and neuropathy. Additional research is needed to determine the basis for genetic susceptibility to micro- and macrovascular complications²⁴⁷ and to develop successful tertiary prevention of hypertension and accelerated atherosclerosis in persons with T1DM.

TYPE 2 DIABETES MELLITUS

Type 2 diabetes mellitus (T2DM), formerly known as non-insulin-dependent diabetes, is the most frequent form of diabetes mellitus in all parts of world. The prevalence of the disease is increasing globally.²⁴⁸ It is estimated that in 2000 there were approximately 150 million individuals with the disease and that this number is likely to double by 2025. In most countries, including those with a high level of medical care, there is typically one undiagnosed case of T2DM for each that is known. Thus, studies that ascertain only previously diagnosed cases are subject to limited interpretation.

As T2DM may remain undetected for many years, investigations of its development, natural history, and complications are compromised when cases are identified only by routine clinical diagnosis. As undiagnosed diabetes represents an important fraction of the population with the disease, most epidemiologic studies are performed by testing all subjects in the population of interest. Without systematic testing, an incomplete and potentially misleading picture of the frequency or distribution of the disease is obtained. Furthermore, because of the differences in criteria, comparisons of rates from recent and earlier studies must be made with caution.

The 1980 internationally accepted WHO criteria for the diagnosis and classification of diabetes led to much greater uniformity

of methods used in epidemiologic studies.^{231,249} Recently, the diagnostic criteria have been revised, thus complicating comparisons of studies that are analyzed according to the new criteria and those that used the 1980 WHO criteria.^{250,251}

Changes in Diagnostic Criteria

The classification and diagnostic criteria for diabetes mellitus were revised by the American Diabetes Association in 1997²⁵⁰ and by the World Health Organization in 1999 (see Chap. 18).²⁵¹ The main changes included the designation of the majority of individuals formerly classified as non-insulin-dependent diabetes mellitus as T2DM mellitus. However, some individuals who fell into this category in earlier classifications were reclassified as Other Specific types of diabetes because the underlying basis for their abnormality of carbohydrate tolerance can now be specifically identified. Several types of non-insulin-dependent diabetes usually presenting in younger adults and widely known as maturity-onset diabetes of the young (MODY) were reclassified because the specific genetic causes of the disease have been identified. Cases of patients with non-insulin-treated diabetes who have circulating autoantibodies, such as islet cell antibodies, glutamic acid dehydrogenase antibodies, or insulin auto-antibodies, or HLA-DR types typically associated with T1DM, are now classified as T1DM. Diabetes of the category formerly known as malnutrition-related diabetes is now subdivided into those with fibrocalculus pancreatopathy, reclassified among Other Specific types of diabetes, whereas the remainder of patients without this specific feature now are considered to have T2DM. Thus, T2DM represents diabetes in the absence of T1DM or Other Specific types of diabetes. Nonetheless, the vast majority of diagnosed and undiagnosed diabetes in most populations falls into the T2DM category.

The revised diagnostic criteria accord greater importance to the fasting plasma glucose concentration (FPG) as a criterion for diagnosis, with the value considered diagnostic of diabetes lowered to greater than or equal to 126 mg/dL or 7.0 mmol/L.^{250,251} In addition, a category or clinical stage of diabetes called impaired

fasting glycemia (IFG) was introduced to categorize individuals who have fasting plasma glucose levels that are abnormal but fall short of the new diagnostic fasting plasma glucose level for diabetes, that is, FPG = 110 mg/dL (6.1 mmol) –125 mg/dL (<7.0 mmol/L). The category of impaired glucose tolerance (IGT) was retained. These changes in diagnostic criteria have resulted in some individuals being reclassified as having diabetes, that is, individuals with FPG levels at or above 126–139 mg/dL and with post-load 2-hour glucose values of less than 200 mg/dL, thereby resulting in an increase in prevalence.²⁵² Furthermore, some recent papers have reported prevalence of diabetes based solely on fasting glucose values rather than on the 2-hour value based on oral glucose tolerance testing.

While the category of impaired glucose tolerance has been recognized as a risk category for the past 20 years, the category of impaired fasting glucose is new. Furthermore, it is now apparent that less than a majority of individuals with impaired glucose tolerance have impaired fasting glucose, and conversely, less than a majority of those with impaired fasting glucose have impaired glucose tolerance (see Chap. 18).^{252,253}

Prevalence

The prevalence of T2DM varies enormously in different countries and among different racial and ethnic groups (Fig. 19-8).²⁵⁴ Dramatic increases in the prevalence and incidence of T2DM have occurred in many parts of the world, especially in the newly industrialized and developing countries. Indeed, the majority of cases of T2DM in the future will occur in developing countries, with India and China having the highest number of cases in the world.²⁴⁸

Estimates have been made of the likely increases in the prevalence of diabetes over the next 20 years. Based on demographic changes, such as the increase and aging of populations, as well as trends in rural to urban migration, it is estimated that the prevalence of diabetes will approximately double in the next 25 years.²⁴⁸

T2DM in developed countries most often occurs in the middle to older age groups. In developing countries, because of the

younger age distribution of the population, many cases occur in young to middle-aged adults. The disease, however, can develop in childhood or adolescence and its occurrence in these age ranges appears to be increasing rapidly especially in populations that already have a high overall prevalence of T2DM.²⁵⁵ In Caucasian populations, in the United States and Europe the prevalence of T2DM increases with age at least into the seventies.²⁵⁶ Prevalence, however, represents the balance between the cumulative rate of development of new cases (cumulative incidence) and the effect of excessive mortality among those with the disease. Furthermore, the patterns seen in prevalence data can be influenced considerably by secular changes in the incidence of the disease.

In the United States, the most complete information on the prevalence of T2DM has been obtained from the U.S. National Health Examination Surveys.^{257,258} Surveys carried out in persons age 20–74 years in representative samples of the U.S. population show that the prevalence differs considerably in different ethnic groups.^{258,259} The prevalence in Hispanic Americans, particularly Mexican Americans, is higher than in the white or black populations and African-Americans have a greater prevalence than whites.²⁶⁰ Native American populations have a prevalence of T2DM even higher than Hispanic and African-Americans, although the prevalence does vary from one tribal group to another.^{261,262} The exception to this appears to be among Eskimos, who have a prevalence no higher than white Americans.²⁶¹

Data from the health examination surveys (NHANES III) conducted between 1988 and 1994 showed that 5.1% of U.S. adults age 20 years and over already carried a diagnosis of diabetes.²⁵⁷ The prevalence of undiagnosed diabetes, based on fasting plasma glucose levels of 126 mg/dL or higher, was 2.7%, or based on glucose tolerance tests and the 1985 WHO criteria, was 6.3%.²⁵² The total prevalence was 7.8% based on diagnosed diabetes and fasting plasma glucose levels only, or 11.4% when based on the 1985 WHO criteria, rates appreciably higher than seen in earlier surveys. Among persons age 40–74 years the prevalence (based on the fasting criteria) had increased from 8.9% in 1976–1980 to 12.3% in 1980–1994—a 38% increase over the course a decade. Data from the Behavioral Risk Factor Surveys, carried out on representative samples of U.S. adults by telephone interviews, indicate that the prevalence of diagnosed diabetes in those aged 18 years and over has continued to increase between 1991 and 1999 from 4.1 to 6.0% in men, and from 5.6 to 7.6% in women, an increase of approximately 40% in less than a decade.^{263,264}

Increases in T2DM have been observed in many other populations in the past half-century. For example, among the Pima Indians a 40% increase in the prevalence occurred between 1967 and 1977, primarily due to an increase in the incidence (the rate of development in new cases) of the disease.²⁶²

Prevalence of Diabetes in Other Countries

The prevalence of T2DM varies considerably among populations of different ethnic origins living in similar environments.²⁶⁵ For example, in Singapore, the frequency of diabetes in 1992 was 8.5%—7.7% in Chinese men and women aged 18–69 compared to 13.3% and 12.3%, respectively, among the Asian Indians and Malays.²⁶⁶ High prevalence rates of diabetes have also been found among Asian Indians compared to the indigenous populations in the United Kingdom, Fiji, and the Caribbean.²⁶⁷ Considerable differences in the prevalence of diabetes have also been described among

FIGURE 19-8. Prevalence of diabetes according to 1980 WHO criteria in men and women aged 30–64 years in different countries and various ethnic groups. (Adapted from reference²⁵⁴)

Adapted from King H et al. Diabetes Care 16:157-177, 1993

the multi-ethnic populations of Hawaii and New Zealand, where the Native Hawaiian and Maori populations, both of Polynesian origin, have higher prevalences than other ethnic groups.²⁶⁸ Such differences support to the notion that there are racial and ethnic differences in the inherent susceptibility to develop T2DM. Nevertheless, there is also clear evidence that T2DM prevalence varies according to socioeconomic, educational, and other acquired characteristics so that differences in the prevalence of the disease in different ethnic groups living in the same location may be attributable to factors other than genetic predisposition to the disease.

T2DM in Children and Adolescents

T2DM was formerly considered as a disease of adults. In recent years, however, there have been many reports of its occurrence in childhood and adolescence.^{255,269,270} As in adults, the disease in children is frequently asymptomatic and is detected mainly by screening. In Japan, a national program for screening school children has been in place since 1992 and the number recognized to have T2DM has increased progressively so that the prevalence and incidence of T2DM greatly exceed those of T1DM.²⁷¹ Adolescent T2DM was first described among the Pima Indians²⁷² and the prevalence has increased steadily over the past 30 years (Fig. 19-9).²⁶⁹ Reports of T2DM in this age group have appeared from many ethnic groups in recent years, including other Native American tribes, Mexican Americans, African-Americans, Chinese, Polynesians, Asian Indians, and Arabs from the Gulf States. There are few reports among Caucasians, suggesting that the condition is still relatively rare in this ethnic group.

T2DM in childhood and adolescence is associated with obesity and parental diabetes, and in the Pima Indians, about a third of the affected are offspring of mothers who had diabetes during pregnancy.²⁶⁹ It is also associated with the development of the same vascular complications as are seen in adults, but at an earlier age.²⁷³

Incidence

Incidence is the rate of development of new cases of disease. Only a few studies of the incidence of T2DM using standardized and comparable methodology have been reported. One method to determine the incidence in a specific population is to test glucose tolerance at two separate points in time and then estimate the cumulative incidence within the interval between the tests. Another method involves multiple tests at regular intervals over a period of time. By this method, the date of onset of disease can be estimated

and the incidence density rate (new cases per person-year at risk can be calculated.

A less desirable, but easier method of estimating the change in the incidence of T2DM has been used to examine if there has been a secular increase in the incidence of diabetes in the general U.S. population. In the National Health Interview Survey, the question of whether diabetes has been diagnosed during the past 12 months has been asked on several occasions. The prevalence of diagnosed diabetes and the rate of new diagnoses reported within the previous 12 months, have increased remarkably over time.²⁵⁴ Some of this increase is undoubtedly attributable to the more frequent and widespread use of blood tests for glucose in routine medical care, but the continuing increase strongly suggests that the incidence of diabetes has risen considerably in the United States since 1940. Incidence studies using standardized glucose tolerance tests have been performed in the Pima Indians of Arizona^{274,275} and among Micronesians in the central Pacific island of Nauru.²⁷⁶ Both groups have very high incidence rates. Among Pima Indians, the age-specific incidence and aged-adjusted incidence rates of diabetes have increased over the course of two decades,²⁷⁷ whereas in Nauru, the incidence may now be falling.

Mortality

T2DM is associated with excess mortality, mainly attributable to the vascular complications of the disease. In Caucasian populations, much of the excess mortality is attributable to cardiovascular disease, especially ischemic heart disease,²⁷⁸⁻²⁸⁰ but in others, such as Asian and American Indian populations, renal disease contributes to a considerable extent.^{281,282} In developing nations, an important component of the excess is due to infections.²⁸³

Age-adjusted mortality rates among persons with diabetes are 1.5–2.5 times higher than in the general population,²⁷⁸ but the excess is greater in younger age groups and diminishes at older ages. The excess mortality leads to reduced life expectancy among those with T2DM.^{284,285} The extent of the reduction of life expectancy is dependent on the age of onset of the disease, but averages approximately 10 years in countries such as the United States. Mortality in women is generally lower than in men, but the relative risk of death in women with diabetes is increased so that the absolute rates approach those seen in men with T2DM.^{286,287}

The increased mortality in patients with T2DM is seen mainly among those with complications. Risk factors include proteinuria and retinal disease, and the classic risk factors for heart disease. Hyperlipidemia, hypertension, and smoking, each contribute disproportionately to death rates among those with T2DM.²⁸⁸ Mortality rates also increase with increasing duration of the disease.²⁸⁵

Risk Factors

Familial Aggregation

The empiric risk of having T2DM is increased two- to sixfold if a parent or sibling has the disease.²⁸⁹ Consequently, a positive family history is a practical, albeit crude, way of estimating if an individual is likely to have inherited susceptibility to the disease. On the other hand, familial aggregation may occur for nongenetic reasons. Family members often share a similar environment, particularly as children and in adolescence thus familial aggregation alone is not definitive evidence of genetic determinants. Furthermore, with a disease as frequent as T2DM two or more family members may well have the disease by chance alone.

FIGURE 19-9. Changes in prevalence of type 2 diabetes in Pima Indian children and adolescents over a 30-year period. (From reference²⁶⁹)

Genetic Factors

Twin Studies

A higher degree of concordance for T2DM in identical twins than in dizygotic twins provides strong evidence that genetic factors are important in determining susceptibility,^{290,291} even though twins share the same intrauterine environment and usually grow up in a similar environment. Nevertheless, the high degree of concordance among twins *per se* does not indicate that the majority of individuals who carry genetic susceptibility will develop the disease; thus, among identical twins, there may be pairs who carry the genetic susceptibility and may never manifest the disease.

Further evidence of the importance of genetic factors as predisposing factors for T2DM comes from studies of admixed populations. Differences in prevalence among persons of mixed racial background from that in parent populations with notably different prevalences of the disease are indicative of the importance of genetic determinants. Such relationships have been described among Nauruans and Pima Indians where full-heritage members of these groups have significantly higher rates of diabetes than those of mixed heritage (Fig. 19-9).^{292,293} Similarly, among the Mexican American population of San Antonio, the prevalence of T2DM is related to the degree of American Indian admixture, with higher rates associated with greater proportions of American Indian genes.²⁹⁴

Genes

Genes that specifically confer risk for the development of T2DM have been identified only to a limited extent. Genes have been identified that determine susceptibility to several rare forms of monogenic diabetes, such as MODY, that were formerly classified as non-insulin-dependent diabetes. Many patients with such forms of diabetes may still be inaccurately diagnosed as T2DM unless specific attempts are made to identify them. These monogenic forms of diabetes, now classified as Other Specific types of diabetes, are discussed in Chap. 21.

T2DM is a complex genetic disorder. Genomic scans have identified several regions in the genome where putative susceptibility genes are located.²⁹⁵⁻²⁹⁹ Several genomic scans have indicated the presence of a locus or loci on chromosome 1, but apart from this region, there is limited consensus concerning the likely location of others. These observations suggest that the common forms of T2DM are multigenic and that the relative importance and frequency of the genes determining susceptibility varies from population to population. Certain haplotypes of the calpain 10 gene in the Mexican American population of Starr County, Texas,³⁰⁰ and polymorphisms of the PPP1R1 gene in the Pima Indians³⁰¹ have been identified as contributing to susceptibility to T2DM, and polymorphisms in the PPAR γ gene have been reported to interact with dietary fat intake to contribute to physiologic characteristics that predispose to the disease (see Chap. 21).³⁰²

Modest associations of HLA type and T2DM have been reported in the populations of Pima Indians, Nauru, Asiatic Indians in Fiji, and in the Finnish population.^{292,303,304} This chromosomal region, however, has shown no definite evidence of linkage in the genomic scans, and in marked contrast to T1DM, seems likely to have only a minor role in contributing to susceptibility in T2DM.

Age and Sex

The prevalence and incidence of T2DM vary to some extent between the sex from one population to another, but these differences are relatively small and appear to be accounted for by differ-

ences in other risk factors, such as obesity and physical activity. The prevalence of T2DM increases with age, although these patterns of incidence vary considerably. In populations with high frequencies of the disease, the incidence may be high and the prevalence may increase markedly in the younger adult years (e.g., 20–35 years of age); in others, the incidence and prevalence increase mainly in older individuals (e.g., 55–74 years of age). In most populations a decrease in prevalence is seen in the oldest age groups (e.g., 75+ years) because of higher mortality rates in those with T2DM.

Prevalence rates, however, reflect the balance between the rate of development of new cases (incidence), the duration of disease and mortality. Thus, secular changes in the incidence of the disease can have a marked influence on age-specific patterns of prevalence in different populations and in the same population over different time periods.

Incidence rates provide a much more accurate reflection of changing patterns of disease, but only a limited number of studies have measured age- and sex-specific incidence rates for T2DM. Such rates vary considerably according to other risk factors. Figure 19-10 shows the differences in age-specific incidence rates according to body mass index (BMI) in the Pima Indians.²⁷⁵ Those with higher BMI have much higher incidence rates of T2DM at earlier ages than those with lower BMI, among whom the incidence rises in the older age groups.

Obesity

Obesity is a frequent concomitant of T2DM. In many longitudinal studies, it has been shown to be a powerful predictor of its development.^{275,305} In nonobese individuals, the incidence of T2DM is low, even in populations such as the Pima Indians where the overall risk of the disease is very high. The relationship of incidence of T2DM to obesity also varies with other risk factors. For example, in the Pima Indians, the incidence rises much more steeply with BMI in those whose parents have diabetes than in those who do not (Fig. 19-11). This relationship indicates an interaction between risk factors.

Several studies indicate that waist circumference or waist-to-hip ratio may be a better indicator of the risk of developing diabetes than body mass index.³⁰⁶⁻³⁰⁸ Such data suggest that the distribution of body fat is an important determinant of risk as these measures reflect abdominal or visceral obesity. In Japanese American men,

FIGURE 19-10. Incidence of diabetes by age group according to body mass index (BMI) in Pima Indian men and women. (Updated from reference²⁶²)

FIGURE 19-11. Age-sex adjusted incidence of diabetes in Pima Indians according to body mass index and whether diabetes was present in both, one or none of their parents. (Adapted from reference²⁷⁵)

for example, the intraabdominal fat as measured by CAT was the best anthropometric predictor of diabetes incidence.³⁰⁷

Obesity has increased rapidly in many populations in recent years. This increase has been accompanied by an increasing prevalence of T2DM. As obesity is such a strong predictor of diabetes incidence, it appears that the rapid increases in the prevalence of T2DM seen in many populations in recent decades are almost certainly related to increasing obesity. Furthermore, interventions directed to reducing obesity reduce the incidence of T2DM in obese individuals with impaired glucose tolerance (*vide infra*).

Physical Activity

Many studies indicate the important role of physical activity in the development of T2DM.^{309–312} Nevertheless, its relative importance may be underestimated in most studies because of imprecision in measurement. Several studies do provide evidence of a causal role of physical inactivity in the etiology of T2DM.^{309,310,312} The deleterious effect of low levels of physical activity is seen particularly among those subjects who have other risk factors, such as high BMI, hypertension, or parental diabetes. For example, in the Nurses Health Study, women who reported exercising vigorously at least once per week had an age-adjusted incidence rate of self-reported clinically diagnosed diabetes that was two-thirds as high as that of women who exercised less frequently.³⁰⁹ Similarly, among male physicians, the incidence of self-reported diabetes was negatively related to the frequency of vigorous exercise, and the strength of this relationship was greater in those with higher BMI.³¹⁰ For equivalent degrees of obesity, more physically active subjects have a lower incidence of the disease (Fig. 19-12).³¹² Intervention studies that have included increased physical activity to prevent diabetes among subjects with impaired glucose tolerance (*vide infra*) demonstrate a reduced incidence of T2DM, but the dose-response relationship of physical activity to diabetes incidence, and the extent that the relationship is confounded by concomitant weight loss, remains unclear.

Gestational Diabetes

Gestational diabetes (diabetes first recognized during pregnancy) is more frequent among women from subgroups of the pop-

FIGURE 19-12. Incidence of diabetes according to baseline level of physical activity and body mass index (BMI) in men. (Adapted from reference³¹²)

ulation who have a high risk of T2DM (e.g., older, overweight or obese women, certain ethnic groups, etc.). In some cases, gestational diabetes represents diabetes that was present, but undiagnosed before pregnancy. In others, it develops during pregnancy, most frequently toward the end of the second trimester. It is in this latter group that glucose tolerance is likely to become normal following delivery, but such women carry a high risk for developing diabetes.³¹³

Other Risk Factors

Genes, obesity, and physical inactivity appear to be the most important risk factors for T2DM. There are, however, others that influence the risk of developing T2DM, but their importance on a population level is much less than those of obesity and physical inactivity. These include low birth weight, exposure to a diabetic intrauterine environment, and other metabolic and environmental exposures.

The relative importance of genetics is difficult to assess in the absence of specific knowledge of the genes concerned. The extent to which the effects of obesity and physical activity vary according to the presence or absence of diabetes in parents indicates that genetic factors are important, but not sufficient, for the development of the disease. The strength of the relationship between obesity and physical inactivity suggests that T2DM is, for the most part, a preventable disease.

Low Birth Weight

Studies in many populations indicate that low-birth-weight babies have an increased risk of developing T2DM in adult life.^{314–318} This relationship was first described by Hales and Barker,³¹⁹ who suggested that low birth weight due to nutritional deprivation *in utero* also resulted in reduced β -cell mass. They suggested that the relationship might represent a “thrifty phenotype”—an acquired rather than inherited defect—that was expressed as T2DM when those with the phenotype were exposed to a more affluent nutritional environment. Low birth weight is also associated with other traits that are associated with the development of diabetes including increased blood pressure, elevated triglycerides, and lower HDL concentrations—all characteristics of the insulin resistance or metabolic syndrome.³²⁰

Low birth weight (and also high birth weight—see the following discussion) is predictive of diabetes among the Pima Indian population.³¹⁵ The fathers, but not the mothers, of low-birth-weight Pima babies have higher rates of diabetes than the fathers of more

usual weight babies, suggesting that the low-birth-weight to diabetes relationship may have a genetic rather than an acquired basis.³²¹ There are certainly paternally derived genes that are linked to low birth weight, but whether or not these same genes predispose the offspring to T2DM remains to be determined. Low-birth-weight children are relatively insulin-resistant and it has also been suggested that the low-birth-weight to diabetes relationship might represent the selective survival of insulin-resistant babies and that this insulin-resistance would later lead to T2DM.³²² In spite of the importance of this relationship in furthering understanding of the complex biology of early life events, the proportion of T2DM in most populations that can be accounted for by low birth weight is relatively small.³²³

Intrauterine Environment

The intrauterine environment influences the risk of developing T2DM. Offspring of diabetic pregnancies develop obesity at an early age and also are at high risk of developing T2DM at an early age (Fig. 19-13).³²⁴ Such individuals have lower insulin secretion than similarly aged offspring of nondiabetic pregnancies.³²⁵

A substantial part of the excess risk of diabetes in the offspring of diabetic pregnancies appears to be the result of exposure to the diabetic intrauterine environment. Among offspring born to mothers before and after the development of T2DM, those born after the mother developed diabetes have a three fold higher risk of developing diabetes than those born before.³²⁶ Thus, the enhanced risk among the offspring from diabetic pregnancies among such women is the result of intrauterine programming that has long-term effects on the offspring in later life.

The early appearance of T2DM in female offspring increases the likelihood that their offspring will be exposed to a diabetic intrauterine environment. This will lead to an increased prevalence of diabetes in subsequent generations.

Inflammation

Several inflammatory markers, such as interleukin 6, C-reactive protein, other cytokines, and acute-phase reactants, such as fibrinogen and plasma activator inhibitor-1 (PAI-1), have been associated with T2DM and its metabolic precursor, insulin resistance.^{327,328} The extent to which these proteins are involved in the pathogenesis of T2DM is not clear. Nevertheless, it has been suggested that T2DM could be a disease of the innate immune system.³²⁹

The epidemiologic support for the hypothesis comes from evidence that C-reactive protein, interleukin-6, and gamma globulin levels are associated with and also predict the development of T2DM.^{327,330} The extent to which these markers are a cause or a consequence of underlying pathogenetic processes is presently uncertain.

Certain infections, such as hepatitis C, have also been associated with T2DM. Patients with hepatitis C infection not infrequently have glucose intolerance. Furthermore, in the NHANES III survey, anti-HCV antibodies were found 3 times more commonly in patients with T2DM than those without, but only about one-third of those with T2DM had such antibodies.^{331,332} There are no prospective population-based studies to indicate whether hepatitis C infection predicts the development of T2DM or how much of the disease might be attributable to this infection.

Sex Hormones

Low levels of sex hormone binding globulin predict the development of T2DM in women but not in men.^{333,334} Furthermore, men with low testosterone levels and women with high levels of androgens are insulin-resistant.³³⁵ Insulin resistance, or hyperinsulinemia, and hyperandrogenemia and nulliparity are also characteristic of the polycystic ovarian syndrome. Nulliparity in the Pima Indians is associated with a higher prevalence of T2DM.³³⁶ The significance of these relationships and the importance of sex hormones as risk factors for T2DM requires further investigation.

Dietary Factors

Breastfeeding is reported to be associated with a lower prevalence of T2DM in young adults.³³⁷ This suggests that dietary factors in early life may program the risk of diabetes in later years.

In spite of obesity being such a strong risk factor for T2DM, the role of dietary factors in the development of T2DM is complex. The prevalence of diabetes has risen in many countries as nutrition and caloric intake have increased, for example, Japan. Conversely, marked reductions in T2DM have been recorded in wartime when caloric and nutritional deprivation have been present.³³⁸ Such observations, however, provide no indication of the role of specific effects of diet in the etiology of T2DM.

Many studies have examined nutritional and calorie intake in persons with T2DM and controls. Few consistent differences have emerged from these studies, which are open to the criticism that the purported differences are a result rather than a cause of the diabetes. There are only a few prospective studies where dietary information has been obtained in cohorts before the onset of diabetes, who were then followed to ascertain the development of diabetes. Some of these studies have been very small and have lacked power to detect any but large effects,³³⁹⁻³⁴² but some suggest that total calorie intake and a low polyunsaturated to saturated fat ratio may predispose to the disease. Recently some large studies, such as Nurses Health Study and the Iowa Study, have examined the effects of dietary intake on the incidence of diabetes.^{343,344} In each of these studies, however, diabetes has been ascertained by self-report of clinically diagnosed diabetes, which likely underestimates the importance of the dietary effects. Furthermore, the lack of precision and poor reproducibility of dietary interviews further reduce the likelihood of detecting important etiologic differences.

The Nurses Health Study involved almost 90,000 women free of diabetes, cardiovascular disease, and cancer at baseline who were followed for 16 years, during which, 3300 new cases of T2DM developed.³⁴³ Higher cereal and fiber intake and higher dietary polyunsaturated to total fat ratios at baseline predicted a sig-

FIGURE 19-13. Prevalence of diabetes in offspring, by age group, according to whether mother had diabetes at time of pregnancy, developed it later, or remained non-diabetic. (From reference³²⁴)

nificantly lower incidence of T2DM, whereas higher consumption of trans fatty acids and foods with a higher glycemic index was associated with an increased risk of the disease. While each of these relationships was significant, the effects were relatively modest with relative risk for diabetes comparing the first and fifth quintiles, ranging from 0.6 for cereal fiber, 0.8 for polyunsaturated to total fat ratio, and 1.4 for trans fat intake and “glycemic load.”³⁴⁵ The relationships were seen across all strata of body mass index. Similar patterns have been seen in other studies. Neither total fat nor total carbohydrate as a proportion of total energy intake appeared to play a major predictive role in the development of T2DM.³⁴⁶

Communities in which there have been rapid changes in the type of diet consumed include many where dramatic changes in the prevalence or incidence of T2DM have been observed (e.g. Pima Indians, Nauru, Japan). In the Pima Indian population, although specific dietary components could not be implicated, individuals stating that they consumed a more traditional “Indian” diet as opposed to a more “Western” or “Anglo” diet experienced less than half the incidence of diabetes over an average 8-year follow-up period.³⁴⁷ Such an effect, however, may reflect other lifestyle factors, rather than diet alone, that may influence the development of the disease, and these may not be adequately or appropriately considered in the analysis of such data.

Dietary intervention studies designed to delay or prevent the onset of T2DM have been conducted on high-risk individuals with impaired glucose tolerance (*vide infra*). Although these studies have shown that the incidence of T2DM can be reduced and that the reduction is a function of weight loss, they provide no information about whether or not dietary changes *per se* are effective, or if specific dietary constituents alter diabetes risk.

Alcohol Intake

Several studies indicated that moderate alcohol intake is associated with a reduced incidence of T2DM. Among women in the Nurses Health Study, there was a reduced incidence of diabetes in women who consumed alcohol compared to those who did not. There was a strong inverse relation between alcohol consumption and body weight, which could explain much of the apparent protective effect of alcohol consumption.³⁴⁸ Among 20,000 male physicians, those consuming more than 2–4 drinks per week had a lower incidence of T2DM in the subsequent 12 years compared to nondrinkers, relationships that persisted after adjustment of BMI and other diabetes risk factors.^{349,350}

These apparent male to female differences were examined among 12,000 45–64-year-old participants in the Atherosclerosis Risk in Communities Study.³⁵¹ After adjustment for other diabetes risk factors, men consuming more than 21 drinks per week had a significant increase in the incidence of diabetes, whereas no significant association with alcohol intake was found among the women. The apparent inconsistencies in the results of these studies suggest that other lifestyle behaviors differ in relation to alcohol consumption in different populations. However, it seems unlikely that moderate alcohol consumption has a deleterious effect on the incidence of T2DM, and may even be associated with a modest degree of protection.

Metabolic Changes During Development of Type 2 Diabetes

The development or worsening of insulin resistance represents a stage in the development of T2DM as reviewed elsewhere (see Chap. 22). Fasting insulin concentrations in subjects with normal

glucose tolerance represent a surrogate marker of insulin resistance, and numerous longitudinal studies have shown that higher fasting insulin levels (or other indices of insulin resistance, e.g., HOMA) predict the development of T2DM. The effect of obesity on T2DM risk is probably mediated by its effect to worsen insulin resistance. Insulin resistance is also influenced by physical activity, with lower levels of activity being associated with greater insulin resistance. Consequently, insulin resistance can be considered a mechanism through which many of the risk factors for T2DM exert their pathophysiologic effects (Figure 19-14).³⁵²

Other factors that increase the risk of T2DM, such as low birth weight, sex-hormone abnormalities, polycystic ovarian syndrome, and inflammatory markers, are all associated with insulin resistance. Component factors of the insulin-resistance or metabolic syndrome also predict the development of T2DM. These include increased blood pressure, raised triglyceride and low high-density lipoprotein concentrations, and obesity and central or visceral adiposity.

Insulin resistance can be identified before any discernable effects on fasting plasma glucose or glucose tolerance can be detected. As insulin resistance worsens, glucose homeostasis may become abnormal and impaired glucose tolerance develops. Marked fasting hyperinsulinemia is characteristic of this stage of the development of T2DM.³⁵³ Impaired or deteriorating β -cell function leads to inadequate insulin secretion to compensate for the insulin resistance and glucose intolerance develops (see Chap. 21).

Impaired glucose tolerance (IGT) and impaired fasting glycemia (IFG) represent clinical stages in the development of T2DM. Both IGT and IFG predict the development of T2DM.^{354–356} Data relating to IGT are more numerous, as it was first defined in 1979, whereas IFG was defined only in 1997.

IGT is associated with a high risk of developing T2DM.^{357,358} Persons with IGT typically have relatively high BMI, fasting hyperinsulinemia, and various features of the metabolic syndrome. IGT can be considered a further stage in the development of T2DM as a high proportion of those with it progress to T2DM over a period of a few years, although such progression is not inevitable.³⁵⁸ IGT is associated with a marked degree of insulin resistance and impaired insulin response to the challenge. Progression to T2DM from IGT is most often associated with further worsening of β -cell function and the further inability of insulin secretion to compensate for the insulin resistance.³⁵⁹ Conversely, improvement in glucose tolerance may occur with weight loss, either

FIGURE 19-14 Stages and risk factors in the development of type 2 diabetes. (Adapted from reference³⁵²)

as a result of caloric restriction or increased physical activity, which reduces insulin resistance to the degree that insulin requirements fall so that the existing β -cell function is sufficient to improve glucose tolerance.

Impaired glucose tolerance is associated not only with an increased risk of diabetes, but with increased risks of cardiovascular disease (heart disease and stroke), possibly cancer, and increased total mortality.³⁶⁰ The risks for cardiovascular disease are intermediate between those seen in persons with diabetes and those with normal glucose tolerance, but the absolute risks associated with IGT vary from population to population.³⁶¹

Much less is known about the prognostic significance of impaired fasting glucose. A few studies have demonstrated its ability to predict the development of T2DM,^{354,356,362} and it is associated with increased risks of cardiovascular disease and mortality, although not to the same extent as IGT.^{362,363}

Many persons with IGT do not have IFG and vice versa, and some have both. The dissociation in these two manifestations of impaired glucose regulation suggests that they have somewhat different pathophysiologic bases. Studies in persons with monogenic forms of diabetes suggest that IFG is associated with a greater liver glucose production and a larger β -cell insulin secretory defect than IGT.^{359,364} Whether this is true in the general population remains to be established, but may be anticipated in view of the different glucose homeostatic mechanisms that control fasting glycemia and postprandial or post-glucose challenge hyperglycemia.

T2DM Prevention

The prevalence and incidence of T2DM have increased dramatically during the past 50 years in many countries. Countries such as Japan and India that used to have low prevalences now have rates that exceed those found in the United States and Europe. In the United States, the rates have increased considerably in the past 30 years and have continued to do so over the past decade.^{256,365}

In 1962, the relatively high frequency of diabetes in populations was proposed to be the result of a "thrifty genotype."³⁶⁶ As diabetes has a strong genetic basis, it was proposed that the high prevalence was the result of a genotype that had selective advantage at the time when human populations were subject to alternating cycles of feast and famine, but this genotype became deleterious, and gave rise to T2DM, once food supplies become abundant and periodic famines no longer occurred. The rapid increase in T2DM in the past century can only be attributed to changes in lifestyle, primarily increasing obesity and decreasing physical activity. Thus, the thrifty genotype hypothesis provides a plausible explanation of why a disease that has such strong genetic susceptibility determinants has increased markedly in frequency.

As important lifestyle factors have been identified and groups of persons at high risk are identifiable, several recent randomized controlled clinical trials have examined whether or not lifestyle intervention or pharmacologic interventions can reduce the incidence of T2DM.

Studies in DaQing, China, among 530 persons with IGT were the first to show that lifestyle interventions could reduce the rate of progression to diabetes.³⁶⁷ The effects of diet alone, exercise alone, and both diet and exercise together reduced the incidence of diabetes by about 30% over a 6-year period compared to a control group who received only general lifestyle change recommendations. There was no significant difference among the three intervention groups.

A study from Finland also demonstrated that lifestyle changes reduced the incidence of T2DM among overweight individuals with IGT.³⁶⁸ Specific dietary goals were given and a target of at least 30 minutes of exercise per day was set. Compared to the control group, who lost 0.8 kg over a 2-year period, the intervention group lost 3.5 kg. After an average of 3.2 years, the incidence of diabetes in the lifestyle intervention group was 58% lower than in the control groups.

A much larger multicenter study, the Diabetes Prevention Program (DPP),^{369,370} was conducted in the United States among subjects with IGT and BMI ≥ 24 kg/m² or higher. This study showed a 58% reduction in the incidence of T2DM over a 3-year period in the lifestyle intervention group (Fig. 19-15).³⁷¹ One-third of the subjects were randomized to metformin treatment. This therapy resulted in a 31% lower incidence of T2DM, significantly less than in the placebo group, but the lifestyle intervention was significantly more effective overall than the metformin intervention.

Another multicenter study (STOP NIDDM), also among subjects with IGT, examined whether an α -glucosidase inhibitor, acarbose, delayed (or prevented) the onset of T2DM.³⁷² This study reported a 25% reduction in the incidence of T2DM over a 3-year period. However, as the Finnish study, the DPP, and the STOP NIDDM trials were conducted in rather different ways, and the characteristics of the randomized individuals varied to some degree, direct comparisons of effectiveness cannot be made, except in the DPP, where a head-to-head comparison of lifestyle and metformin treatment was made.

Yet another intervention study (TRIPOD; Troglitazone in the Prevention of Diabetes) examined the effect of a thiazolidinedione, troglitazone, on the development of T2DM in women with previous gestational diabetes.³⁷³ Although this trial was stopped prematurely because of the withdrawal of troglitazone from the market, a 50% reduction in the incidence of T2DM was seen compared to the placebo treatment. This trial, therefore, suggests that other thiazolidinedione drugs might also be effective in delaying or preventing the onset of T2DM. Such trials have recently been initiated.

Other pharmacologic agents may also reduce the incidence of T2DM. Secondary analyses of the WOSCOPS (West of Scotland Cardiovascular Disease Prevention Study)³⁷⁴ and the HOPE (Heart Outcomes Prevention Evaluations) study³⁷⁵ suggest that the incidence of T2DM may be lower in patients receiving a statin, pravastatin,

FIGURE 19-15. Results of the Diabetes Prevention Program: diabetes incidence was reduced in persons with impaired glucose tolerance randomized to metformin and to life-style intervention. (Adapted from reference³⁷¹)

tatin, or ramipril, an angiotensin-converting enzyme inhibitor, than among those receiving placebo. Further trials are required to determine if this is indeed true.

The Pathophysiology and Genetics of Type 1 (Insulin-Dependent) Diabetes

Ramachandra G. Naik

Åke Lernmark

Jerry P. Palmer

The term **diabetes** does not denote a single disease entity, but rather a clinical syndrome. Fundamental to all types of diabetes is impairment of insulin secretion by the pancreatic β cells. Except for the β -cell loss that results from known toxins, such as streptozotocin, alloxan, and the rodenticide VacorTM, and from pancreatitis or surgical pancreatectomy, we lack a full understanding of the pathogenic mechanisms leading to diabetes. A major requirement for epidemiologic and clinical research and for the clinical management of diabetes is an appropriate system of classification that provides a framework within which to identify and differentiate the disease's various forms and stages. Although many nomenclatures and diagnostic criteria had been proposed for diabetes, no generally accepted systematic categorization existed until the National Diabetes Data Group (NDDG) classification system was published in 1979.¹ The World Health Organization (WHO) Expert Committee on Diabetes in 1980 and, later, the WHO Study Group on Diabetes Mellitus endorsed the substantive recommendations of the NDDG.¹ These groups recognized two major forms of diabetes, which they termed insulin-dependent diabetes mellitus (IDDM; type 1 diabetes) and non-insulin-dependent diabetes mellitus (NIDDM; type 2 diabetes). However, their classification system went on to include evidence that diabetes mellitus was an etiologically and clinically heterogeneous group of disorders that share hyperglycemia in common.

It is now considered particularly important to move away from a system that appears to base the classification of the disease largely on the type of pharmacologic treatment used in its management and toward a system based on disease etiology. An international Expert Committee, working under the sponsorship of the American Diabetes Association, was established in May 1995 to review the scientific literature since 1979 and to decide whether changes to the classification and diagnosis of diabetes were warranted. The Expert Committee carefully considered the data and rationale for what was accepted in 1979, along with research findings of the last 18 years, and proposed changes to the NDDG/WHO classification scheme.²

The main features of these changes are as follows. The terms insulin-dependent diabetes mellitus and non-insulin-dependent diabetes mellitus and their acronyms, IDDM and NIDDM, were eliminated. These terms have been confusing and have frequently

resulted in classification of the patient based on treatment rather than etiology. The terms type 1 and type 2 diabetes are retained, with Arabic rather than roman numerals. The class (or form) termed **type 1 diabetes** (T1DM) includes the vast majority of cases that are primarily due to pancreatic islet β -cell destruction and that are prone to ketoacidosis. This form includes those cases currently ascribable to an autoimmune process and those for which an etiology is unknown. It does not include those forms of β -cell destruction or failure for which non-autoimmune-specific causes can be assigned (e.g., cystic fibrosis). Although most type 1 diabetes is characterized by the presence of autoantibodies that identify the autoimmune process leading to β -cell destruction, in some subjects, no evidence of autoimmunity is present; these cases are classified as type 1 idiopathic. The other main class (or form), termed **type 2 diabetes** (T2DM), includes the most prevalent form of diabetes, which results typically from an interaction between insulin resistance and an insulin secretory defect. Although the exact cause(s) of the insulin resistance and the insulin secretory defect are not known, both are strongly genetically determined, and the β -cell defect does not have an autoimmune etiology.

Epidemiologic studies have suggested that the incidence rate of T1DM peaks twice, once close to puberty and again around 40 years of age,³ and it has been suggested that the overall incidence rate of T1DM is approximately equivalent above and below the age of 20 years.³ Many of these older patients, especially early in the course of their diabetes, are clinically similar to classical T2DM patients. This relatively high incidence rate of type 1 diabetes in adults is often not appreciated, probably because of the over 10-fold greater frequency of T2DM in this age group. Furthermore, the finding of antibodies characteristic of T1DM such as islet cell antibodies (ICA) and glutamic acid decarboxylase antibodies (GADA) in 10–15% of T2DM patients⁴ suggests that in older individuals the type 1 disease process may result in a similar clinical phenotype as the type 2 disease process. This subset has been variously described as latent autoimmune diabetes in adults (LADA),^{5,6} slowly progressive T1DM,⁷ latent T1DM,⁸ late-onset T1DM, antibody-positive T2DM, and type 1½ diabetes.^{9,10} It is believed that the autoimmune β -cell destructive process proceeds more slowly than in young patients with T1DM, but this has not been carefully evaluated.¹¹

The earliest accounts of diabetes mellitus, written more than a thousand years ago, already took different clinical forms into account, and it was suggested in the preinsulin era that the immune system might be involved in the development of some forms of diabetes mellitus (for review, see ref. 12). The presence of inflammatory cells in the islets of Langerhans was later termed "insulinitis."¹³ The significance of this insulinitis at the clinical onset of insulin-dependent diabetes was first studied in detail by Gepts and LaCompte.¹⁴ Their work is of fundamental importance to our current understanding of T1DM because it showed that the development of T1DM was associated with immunopathologic abnormalities. This chapter deals specifically with T1DM. We discuss what is known and what is controversial about the natural history and the genetic, immunologic, and environmental mechanisms involved in the etiology and pathogenesis of T1DM.

NATURAL HISTORY

Because this chapter deals with the etiology and pathogenesis of T1DM, our discussion of natural history emphasizes events occurring before the development of hyperglycemia or overt clinical T1DM. Because of the acute and dramatic onset of symptoms in most patients, it was previously believed that the disease process underlying T1DM was acute in nature and consequently that individuals were normal or unaffected until shortly before the diagnosis. We now understand that exactly the opposite is usually the case: the T1DM disease process has been active and ongoing for a long period, usually at least several years, before patients develop clinical disease.

Based on data that were mostly obtained by prospective studies of nondiabetic relatives of patients with T1DM, the natural history of T1DM includes the following major components. First, as indicated, there is a long preclinical period. During this time antibodies and T cells reactive with β -cell antigens can be detected, and the immunologic attack on the β cells is occurring. Progressive loss of β -cell function has been observed months to years prior to the onset of clinical T1DM,¹⁵ and hyperglycemia after oral glucose may antedate the diagnosis of clinical T1DM by periods ranging from 3 months to 7 years.¹⁶ Investigators in the ongoing Diabetes Prevention Trial-Type 1 (DPT-1) have recently detected among a cohort of ICA-positive first- and second-degree relatives of T1DM subjects, a group of subjects with T1DM who have a different phenotype. These subjects are asymptomatic, have normal or impaired fasting glucose, but have 2-hour glucose values >11.1 mmol/L on their oral glucose tolerance tests (OGTTs).¹⁷

Second, at least 80–90% of the functional capacity of the β cells must be lost before hyperglycemia occurs. The normal pancreas has a large reserve capacity and this must be depleted before clinical T1DM becomes manifest. Because even our most sensitive tests of β -cell function remain normal until islet insulin content is very low,¹⁸ the immune markers of T1DM usually antedate evidence of β -cell insulin secretory deficiency by a long period. Until very recently it was believed that β -cell destruction was the primary mechanism responsible for the loss of insulin secretory capacity during the preclinical period of T1DM. We now recognize, as will be discussed in more detail subsequently, that at least some of the impairment in insulin secretion may be functional and due to inhibition of insulin secretion by cytokines and possibly other factors (reviewed in ref. 19).

Third, as implied by the insulinitis and the presence of antibodies and T cells directed against islet antigens, the β -cell lesion is autoimmune in nature, and fourth, this autoimmune destructive process specifically occurs in genetically susceptible individuals.

In neonatal rodents, the β -cell mass is believed to undergo a phase of remodeling that includes a wave of apoptosis. Using both mathematical modeling and histochemical detection methods, Trudeau and colleagues²⁰ have demonstrated that β -cell apoptosis is significantly increased in neonates compared with adult rats, peaking at approximately 2 weeks of age. It was also shown that increased neonatal β -cell apoptosis is also present in animal models of autoimmune diabetes, including both the BB rat and non-obese diabetic (NOD) mouse. Recent studies indicate that apoptotic cells can display autoreactive antigen in their surface blebs, preferentially activate dendritic cells capable of priming tissue-specific cytotoxic T cells, and induce the formation of autoantibodies, thereby challenging the dogma that apoptosis does not elicit an immune response.²⁰ Initiation of β -cell-directed autoimmunity in murine models appears to be fixed at approximately 15 days of age, even when diabetes onset is dramatically accelerated. Taken together, these observations have led to the hypothesis that the neonatal wave of β -cell apoptosis is a trigger for β -cell-directed autoimmunity.²⁰

T1DM is not a disease of unbridled β -cell destruction. The autoimmune attack on pancreatic β cells has two distinct stages (insulinitis and diabetes), and progression of the former to the latter appears to be regulated. This has been shown in studies in NOD mice. Starting around 5 weeks of age, NOD mice develop a progressive mononuclear cell infiltration in and around the pancreatic islets. This infiltrate will eventually evolve into a destructive insulinitis in those mice progressing to diabetes. By 18–24 weeks of age, most female mice are overtly diabetic. When pancreatic islets with insulinitis were isolated from female NOD mice at different ages (5–7, 8–11, or 12–13 weeks), the islets showed a deficient glucose-induced insulin release and defective glucose metabolism that progressively worsened with age.^{21,22} The observed β -cell dysfunction showed a close correlation to the severity of the mononuclear cell infiltration and was accompanied by defective glucose metabolism. It is not very clear whether humans have such clear-cut stages as in the NOD mice. Identifying the factors controlling this transition has been difficult because it is a complex process that occurs nonuniversally and asynchronously.²³

A major question pertaining to the natural history of T1DM centers around whether the diabetogenic process, once initiated, is relentlessly progressive and always culminates in clinical T1DM, or whether it is more variable, waxing and waning, and sometimes remitting without eventual progression to overt T1DM (Fig. 20-1).²⁴ Whether one or more of the immune markers of T1DM are the direct result of the immune attack and β -cell damage, or possibly are independent of the immune attack, is unknown. In the NOD mouse, for example, although insulinitis is usually considered indicative of the T1DM disease process, it is now recognized that insulinitis can occur in animals that will not develop clinical T1DM.²⁵ Therefore, in considering the available human data, it is important to remember that changes in immune markers may not always be reflective of changes in the immune attack on the β cells. ICAs, especially when detected in low titer, may fluctuate over time (26); although it was initially believed that other antibodies such as insulin autoantibodies (IAAs), GADA's, and insulinoma-associated protein-2 antibodies (IA-2A) vary only

FIGURE 20-1. Hypothetical courses of pancreatic function after islet insult. Inexorable linear decline in function after islet insult leading to rapid onset of clinical disease (---). In: Marshall SM, Home PD, eds. *The Diabetes Annual*/8. Elsevier; 1994;21.)

slightly when measured over several years,²⁷ more recent data show similar fluctuations as for ICA.^{28–35} In nondiabetic individuals with autoantibodies directed against islet antigens, impaired β -cell function is very common. A combination of immune markers with impaired β -cell function is associated with a greater risk of subsequent clinical T1DM than immune markers in combination with normal β -cell function. However, impaired β -cell function is also common in ICA-negative relatives of T1DM patients.³⁶ Because less than 20% of these individuals would be expected to progress to clinical T1DM, these observations suggest that in many of these individuals the β -cell destructive process has remitted.

In identical twins discordant for diabetes, activated T lymphocytes, ICAs, carbohydrate intolerance, or hyperproinsulinemia are more common in those nondiabetic individuals discordant for a short time vs. those discordant in the long term.³⁷ Furthermore, β -cell dysfunction is common in long-term discordant identical twins who were ICA-negative at the time of study, but who previously had been ICA-positive.³⁸ Previous studies suggested that after 6 years of discordance, identical twin pairs rarely become concordant for T1DM.³⁹ With up to 39 years of follow-up from the onset of diabetes in the index twin, Verge and colleagues⁴⁰ have determined how many discordant twins have evidence of β -cell autoimmunity and how many develop overt diabetes. Longitudinal follow-up of 23 pairs of identical twins (or triplets) that were selected from a total group of 30 pairs because they were discordant for T1DM when first ascertained showed that identical twins may develop diabetes after a prolonged period of discordance, and approximately two-thirds of long-term discordant twins have evidence of persistent β -cell autoimmunity and/or β -cell damage. The concordance for β -cell autoimmunity, therefore, is much higher than for overt diabetes.⁴⁰

It should be stressed that the natural history of preclinical T1DM has been described primarily in prospective studies of first-degree relatives of T1DM patients, including the German

BABYDIAB study,^{28,30,31} the Diabetes Autoimmunity Study in the Young (DAISY),^{41–43} and the Childhood Diabetes in Finland Study.^{32–34} This approach has provided a better understanding of the sequence of events preceding the development of hyperglycemia in such individuals.

The temporal development of autoantibodies has been studied in 1353 offspring of parents with T1DM in the German BABY DIAB study.³¹ ICA, IAA, GADA, and IA-2A levels were measured at birth, 9 months, 2 years, and 5 years of age. At birth, no offspring had islet autoimmunity other than maternally acquired antibodies. Antibodies detected thereafter were likely to represent a true *de novo* production, since prevalences were the same for offspring from mothers and fathers with diabetes, antibodies detected at 9 months were almost always confirmed in the 2-year sample, and their presence was associated with an increased likelihood of having or developing other antibodies. By 2 years of age, autoantibodies appeared in 11% of offspring, 3.5% having more than one autoantibody. IAAs were detected most frequently, and few had autoantibodies in the absence of IAAs. Development of additional antibodies and changes in levels, including decline of IAAs at older age, was frequent. Overall cumulative risk for disease by 5 years of age was 1.8% (95% CI 0.2–3.4) and was 50% (95% CI 19–81) for offspring with more than one autoantibody in their 2-year sample. It was concluded that autoimmunity associated with childhood diabetes is an early event and a dynamic process, that the presence of IAAs is a consistent feature of this autoimmunity, and that IAA detection can identify children at risk. The group further reported that the humoral autoimmune response to GAD is initially against epitopes within the middle portion of GAD-65 and spreads to epitopes in other regions of GAD-65 and GAD-67²⁸ (see the Autoantibodies section below).

The Childhood Diabetes in Finland Study Group analyzed 747 children (younger than 15 years of age with newly diagnosed diabetes) for antibodies to GAD, IA-2 protein (IA-2A), insulin (IAA), and islet cells. The aim was to evaluate the influence of positivity for GADA, IA-2A, IAA, or multiple (≥ 3) autoantibodies at diagnosis on the clinical presentation and natural course of the disease over the first 2 years and to characterize autoantibody-negative patients.³² At diagnosis, 73.2% of the children tested positive for GADA, 85.7% for IA-2A, 54.2% for IAA, and 72.6% for multiple autoantibodies. The patients testing positive for multiple autoantibodies were younger than the remaining children ($p < 0.001$). A similar age difference was seen when comparing IAA-positive and -negative patients ($p < 0.001$). They further showed that positivity for multiple diabetes-related autoantibodies is associated with accelerated β -cell destruction and an increased requirement for exogenous insulin over the second year of clinical disease, indicating that multiple autoantibodies reflect a more aggressive progression of β -cell destruction. Patients testing negative for diabetes-associated autoantibodies at diagnosis seem to have a milder degree of β -cell destruction, but their metabolic decompensation is similar to that seen in other affected children, suggesting that they do represent classical T1DM.^{32–34} Mrena and coworkers³⁵ studied a total of 801 families taking part in the Childhood Diabetes in Finland Study and observed that it is possible to grade siblings of children with newly diagnosed T1DM into categories with significant differences in the subsequent risk of clinical T1DM and time to diagnosis. Such a classification should become clinically useful as soon as effective measures are available for preventing or delaying the manifestation of overt T1DM.

In the antibody-positive T2DM or the LADA group mentioned earlier, although it is believed that the autoimmune β -cell destructive process proceeds rather slowly or that the destruction stops at a "moderate" stage,¹¹ it is still not clear from the literature whether the pathophysiologic mechanism(s) of hyperglycemia is more type 1- or type 2-related or a combination of both the diabetes disease processes. A prospective observation on the natural history of the ICA-positive T2DM patients in Japan⁷ disclosed the characteristic findings, which included a late onset, a family history of T2DM, a slow progression of β -cell failure over several years with persistently positive low-titer ICA, and incomplete β -cell loss. Similar presentations have been described in various other countries including Australia,⁶ Finland,⁵ New Zealand,⁴⁴ the United States,⁴⁵ Hong Kong,⁴⁶ Korea,⁴⁷ China,⁴⁷ Mexico, and Sweden.⁴

The typical patient, however, is generally >35 years old (age at onset 30–50 years) and nonobese (by lower body mass index); the diabetes is often controlled with diet, but within a short period (months to years), metabolic control fails, requiring oral agents, and progression to insulin dependency is more rapid than in antibody-negative, obese patient with T2DM. The eventual clinical features of these patients include weight loss, ketosis proneness, unstable blood glucose levels, and an extremely diminished C-peptide reserve^{7,48}; in retrospect, these subjects possess additional classical features of T1DM, i.e., increased frequency of HLA-DR3 and -DR4, and islet-cell antibody positivity.⁸

A number of recent studies have determined ICA, IAA, and GADA levels, usually individually, in patients with phenotypic T2DM.^{4,5,49} It has been shown that high GADA levels remain for up to 40 years after diagnosis of T1DM,⁵⁰ and there appears to be an ethnic difference in anti-GAD positivity, with higher frequency in Caucasian late-onset T1DM subjects than in adult-onset Asian T1DM patients,^{51,52} suggesting that the adult-onset diabetes in the latter groups is less likely to have an autoimmune component to its pathogenesis. Various studies have shown that patients positive for anti-GAD and/or ICA have a more rapid decline in C-peptide, fail oral agents, and require insulin treatment earlier.^{45,53–55} A recent study⁵⁴ showed that the positive rate for anti-GAD was as high as 23.8% in the nonobese and insulin-deficient patients with sulfonylurea failure, suggesting that autoimmune mechanisms may play an important role in the pathogenesis of secondary failure of sulphonylurea therapy. Thus, loss of β -cell function in approximately two-thirds of phenotypic T2DM subjects can be predicted by anti-GAD and ICA. However, as a result of lower cost and relative ease of performance, and the availability of several simple and robust assays for anti-GAD,⁴⁵ GAD antibodies may provide a practical alternative to ICA assay, particularly in population screening. Early detection of these immune markers of β -cell damage creates the potential for immune modulation to limit such damage.

Our current understanding of genetic abnormalities in late-onset T1DM is still not clearly elucidated. The associations between clinical T1DM and HLA genotype appear in part to be determined by age of diagnosis. Patients with onset after age 15 have a higher percentage of non-DR3/non-DR4 genotypes than patients with childhood T1DM, and those with later onset (>20 years) had a lower percentage of DR3/DR4 genotypes and a higher percentage of DQ0602.⁵⁶ It appears that the T1DM disease process is more aggressive, resulting in clinical presentation at a younger age in individuals with more susceptibility genes and less protective genes, and *vice versa*, the disease process is less aggressive, resulting in clinical presentation at older ages in individuals with less susceptibility genes and/or more protective genes.

GENETIC ASPECTS

Association with HLA

The association between HLA and T1DM (see Table 20-1 for definitions) was first demonstrated for HLA-B8 and/or B15.⁵⁷ Early investigations of these HLA class I molecule specificities were identified by antibodies that were specific for individual alleles or group of alleles. HLA specificities were traditionally defined by serology or by T-lymphocyte proliferation assays such as the mixed lymphocyte culture (MLC) tests. Advancing technologies have allowed a rapid detection of new alleles, and these are now primarily characterized at the genomic level by sequence analysis (see ref. 58 for a detailed review). The HLA molecules have structural similarities to an array of related molecules (Fig. 20-2). The marked polymorphism now explained by gene sequencing is one distinct feature of the HLA complex. Another feature of the HLA class I and II molecule genes encoded on the short arm of chromosome 6 is the phenomenon of linkage disequilibrium. This means that the frequency at which certain alleles are found together on the same haplotype is higher than expected, as calculated from the product of their individual gene frequencies. In other words, certain alleles in a haplotype tend to be inherited together, because the recombination frequency at certain parts of the HLA complex is markedly reduced compared with other parts of the human genome.

The phenomenon of linkage disequilibrium is important when an association between HLA and a disease such as T1DM is analyzed.^{59–61} This approach toward estimating susceptibility to a disease differs from that of genetic linkage. The former is based on a comparison between patients and unrelated healthy controls.⁶² The latter analysis takes advantage of multiple-generation families in which a disease is inherited through generations together with a given allele. Because of linkage disequilibrium, gene markers in close proximity to such an allele would tend to be inherited with the disease. Analysis of linkage is also used when investigating sib pairs, which is necessary in studying T1DM due to the rarity of large, multigeneration families.^{63,64} It is critical to the understanding of T1DM etiology that the majority of new patients do not have a first-degree relative with the disease. It has therefore been extremely complicated to determine the mode of inheritance of T1DM.

Lifetime risks for T1DM (Table 20-2) in first-degree relatives of an individual with T1DM have been calculated to be about 3% for parents, 7% for siblings, and 5% for children.⁶⁵ A recent study including patients at an older age at onset and a longer follow-up than in previous studies indicated that 25% of T1DM patients had

TABLE 20-1. Nomenclature and Abbreviations for HLA Molecules

MHC	Major histocompatibility complex
MHC molecules	Proteins encoded on the short arm of chromosome 6; these proteins are involved in various functions of the human immune response
Class I molecules	The heavy chain (M_r 43,000) is encoded in the HLA-A, -B, and -C loci; the light chain is β_2 -microglobulin, coded for on chromosome 9
Class II molecules	A dimer composed of two transmembrane polypeptide chains (α and β) with M_r 34,000 and 29,000, respectively
Class III molecules	Plasma proteins such as C2 or C4, or cytokines such as tumor necrosis factor (TNF) α and β

at least one affected sibling. Interestingly, about 50% of the second siblings developed T1DM more than 10 years after the first affected sibling.⁶⁶ The lifetime recurrence risk for siblings from time of birth up to 30 years of age was 6%, which increased to 10% at 60 years of age. Studies of families with multiple affected members have shown that the occurrence of T1DM is 16% if the parent or sibling shares both HLA markers with the proband (HLA identical), 5% for one HLA marker (HLA haploidentical), and 1% or less for HLA nonidentical.^{59,61} Although these and other studies have failed to clarify the mode of inheritance of T1DM, it is generally held that the HLA types mark genetic susceptibility or risk of developing the disease. This conclusion is based on the calculation of odds ratio or relative risk (RR). This calculation is simply an expression of how often an HLA allele or haplotype occurs in a sample of patients compared with controls. The data may reveal a positive association (interpreted as susceptibility), no association or neutral, or a negative association (interpreted as protection). Certain HLA-DR specificities, such as DR2 (67) or HLA haplotypes such as DQB1*0602-DQA1*0102 (DQ6.2), are rarely found

among young T1DM patients,^{68,69} although the frequency of the haplotype among patients increases with age of diagnosis of diabetes.⁷⁰ The association with the disease is negative, which is interpreted as protection from T1DM. The mechanisms are not fully understood but may be related to a difference in binding of peptides from autoantigens such as GAD.⁷¹

Typing sera defined by international workshops for the serologically defined HLA-DR (R for related) specificities showed that the increased frequencies of B8 and B15 were most likely secondary to increased frequencies of DR3 and DR4 because of the linkage disequilibrium between B8 and DR3 and between B15 and DR4, respectively.⁶⁷ This concept is important for the discussion that follows. Statistical analyses⁶⁷ demonstrate that T1DM patients with HLA-B8 are more often HLA-DR3-positive than healthy HLA-B8 positive controls. These analyses suggested that the DR locus was indeed closer to a putative risk gene for T1DM than the locus coding for the HLA-B specificities. In children or young adults, the overall findings are that >90% of T1DM patients were positive for DR3, DR4, or both compared with 60% of the controls. It was also found that among Caucasians as many as 35–40% of T1DM patients were DR3/4 (heterozygotes).⁶⁷ The calculation of RR or absolute RR for the heterozygous combination DR3/4 exceeds the sum of the RR for DR3 and DR4 either as a homozygous specificity or in association with any other DR type. Monozygotic twins concordant for T1DM showed an increased frequency of DR3/4 heterozygosity.⁷²

Proliferative responses to cloned T lymphocytes in a primed lymphocyte test (PLT) indicate that DR4 has at least six subtypes—Dw4, Dw10, Dw13, Dw14, Dw15, and a Dw-blank specificity. The DR4 specificity is determined by the DRB1 locus.⁷³ Although some controversies exist,⁷⁴ most investigations have shown the Dw4 subtype to be associated with T1DM.⁶⁷ Dw10 was also found to be associated with T1DM, whereas Dw13, Dw14, Dw15, and the blank allele were not.⁷⁵ Cellular typing was rapidly super-

seded by molecular techniques after the cloning of DR and DQ A and B genes (for a review, see refs. 60 and 61). Polymerase chain reaction (PCR) analyses with rapid sequencing are widely used.⁷⁶ These tools make it possible to relate T-cell responses or antigen presentation to different alleles, haplotypes, or genotypes of DR and DQ and to determine the importance of these cellular responses in the pathogenesis of T1DM.

The HLA class II molecules are central to the human immune response because they present peptide antigens to T-helper (CD4-positive) cells (for review, see ref. 77). It is therefore a reasonable hypothesis that HLA class II molecules associated or linked to T1DM may present peptides that are diabetogenic.^{59,61,78} Peptide binding is diverse and variable because there is marked polymorphism of both class I and II molecules. This is of particular importance because class II molecules are dimers composed of one α and one β chain (Fig. 20-2), each coded by a separate gene, and heterodimers can form in heterozygous individuals.⁷⁹ For example, the chromosome inherited from the mother (m) would transcribe an α chain (am) and a β chain (bm). The same transcription events would take place on the chromosome from the father (p), resulting in ap and bp. The class II molecules that may be formed therefore represent ambm, ambp, apbm, or apbp (Fig. 20-3). It is possible that disease-associated class II molecules are formed because of *trans*-complementation events. These events may be positively associated with the disease, such as in individuals with certain DR2/DQ6.2-containing haplotypes, or negatively associated in individuals heterozygous for DQB1*0302 and DQB1*0602.^{68-70,80}

Although DR4 and DR2 are composed of several closely related subtypes, DR3 appears to be more homogeneous.⁵⁸ Compiling the results of a large number of studies, the frequency of DR3 among Caucasian T1DM patients amounts to nearly 60% (range, 20–91%), compared with 22% (10–32%) among healthy controls.^{59,61} The overall RR was 3.4. It is remarkable that the RRs of DR3 in Japan and China (34% in patients and 17% in controls) and among African Americans (57% in patients and 28% in controls) were similar (3.4 and 3.2, respectively). This was also similar to Caucasians (3.4%), even though the absolute frequency of DR3 varies substantially depending on ethnicity. MLC or PLT failed to reveal additional subtypes of DR3 and/or Dw3.⁸¹ In contrast, a

subset of DR3-positive T1DM patients who, in a PLT test, reacted differently from DR3 controls (31% of patients compared with 8% of controls) has been reported.⁸² The DR3 specificity is encoded by the DRB1*0301 gene, which is in linkage disequilibrium with the DQA1*0501-B1*0201 (DQ2) haplotype. The role of DQ2 in T1DM is unclear, especially as it has been found that DQ2 is positively associated with T1DM primarily in the presence of DQ8.⁵⁶

Recent advances in molecular genetics have allowed detailed studies of the genes that code for the HLA class II molecules including their precise chromosomal location, nucleotide sequences, and transcriptional regulation. In fact, the entire HLA class II region has been sequenced, and bioinformatic details are available at <http://www.anthonynolan.org.uk/HIG/index.html>. PCR-based HLA typing has revolutionized not only HLA typing for transplantation, but also studies of disease associations.⁵⁸ Knowledge of the nucleotide sequence permits a derivation of the expected amino acid sequence of the individual class II molecules. A schematic map of the HLA-D region of human chromosome 6 is shown in Fig. 20-4. The reader is referred to refs. 77 and 83 for reviews of the molecular genetics of HLA (Fig. 20-4). The molecular cloning and expression of class II molecules made it possible to determine the structure of these protein complexes,^{84,85} and molecular models are shown in Fig. 20-5. The molecular cloning of these genes has also made it possible to define their functions *in vitro* by gene transfection studies or *in vivo* by the production of transgenic mice. The size of the HLA-D region has been estimated to be as large as 1.1×10^6 bp.⁸⁶ The DQ and DR subregions are harbored within 450×10^3 bp. The current order of known genes from the centromere toward the telomere is illustrated in Fig. 20-4. Each one of the genes, referred to as A and B genes and coding for the α and β chains, respectively, has been cloned and sequenced. Genomic HLA typing by PCR analyses (Table 20-3) made it possible to test the hypothesis that genetic determinants other than DR explained the association between HLA and T1DM. Evidence that DQ is closer to T1DM than DR was first obtained by restriction fragment length polymorphism (RFLP) analysis,⁸⁷ followed by direct cDNA sequence analysis,⁸⁸ and was confirmed in numerous investigations by allele-specific PCR analyses.^{80,89}

As indicated previously, DR4 is a broad serologic specificity now explained by several DRB1 alleles such as DRB1*0401, DRB1*0402, and DRB1*0403.⁵⁸ Due to linkage disequilibrium, these DR4 subtype alleles are commonly inherited with only a limited number of HLA-DQ alleles, as summarized in Tables 20-3 and 20-4. Although DRB1*0401 and DRB1*0405 were strongly associated with T1DM, DRB1*0403 was found to be protective.^{56,90} It is therefore possible that antigen presentation by different HLA-DR or DQ molecules may make variable contributions to T1DM risk.

Taken together, the currently available data suggest that certain DQ alleles are more closely associated with T1DM than the associated DR alleles. Data produced by several investigators suggest that among DR4-positive individuals the DQ8 specificity confers the highest risk for T1DM. This risk may, however, be modulated by different DRB1*04 subtypes.^{56,90} Comparing the DQ β -chain gene sequences between T1DM patients and controls, Todd and coworkers⁸⁸ suggested that susceptibility or resistance to disease is conferred by the amino acid in position 57, as aspartic acid (Asp) in position 57 was rarely seen among diabetic patients. Asp is only one of four polymorphic residues at position 57 of the DQ β chain. The presence of Asp57 in negatively associated HLA-DQ alleles resulted in a simplified view of susceptibility and protection based on this single amino acid.^{88,89,91} Several investigations have since

failed to support this popularized hypothesis. For example, a majority of Chinese⁹² and Japanese⁹³ patients are Asp57-positive on DQ4 and DQ9, which are positively associated with T1DM in these ethnic groups. Other transracial studies⁹⁴ indicated that transcomplementation permits the formation of T1DM -permissive DQ heterodimers despite the presence of DQB1Asp 57. Studies in high-incidence countries such as Norway, Sweden, and Finland demonstrate that 2–3% of T1DM children are homozygous Asp57-positive.⁷⁹

The Asp57 hypothesis was subsequently modified to include the DQA1 locus, and Arg52 of DQA1 was suggested to be a critical residue.^{89,95} Several investigators have used DQB1 Asp57 and DQA1 Arg52 to calculate RR. These analyses show that DQB1 non-Asp57 and DQA1 Arg52 in homozygous combination only accounted for 47% of Swedish T1DM patients compared with 7% of

controls. All other combinations were neutral or negatively associated with T1DM. Not even combining these two polymorphic amino acids would fully explain susceptibility to T1DM. Position 57 is predicted to be at the far right of the lower α helix in Fig. 20-5. However, about 5% of T1DM patients have been found to be positive for DQw7, which has Asp in position 57.^{67,91,96} It is therefore impossible for susceptibility or resistance to T1DM to be conferred solely by this particular amino acid residue.

Large population-based investigations provide sufficient statistical power for the association between HLA and T1DM to be critically analyzed. A genetic factor in the HLA region that totally controlled the development of diabetes would be expected to be present among all (100%) patients. The frequency of this factor in the healthy control population would be expected to be significantly lower, but not necessarily to the level of disease prevalence

itself. Studies in identical twins³⁷ and in families⁹⁷ suggest that the genetic factors may only account for 30–40% of disease susceptibility, the rest probably being the environment. Among the genetic factors, linkage analysis suggests that HLA contributes 60%.⁹⁷

The major question is whether HLA-DQ is the final answer. To answer this question, studies were conducted on both populations and families including sib-pair analyses⁹⁷ using a variety of statistical tests and models to estimate risk.⁶⁸ First, individual alleles may be considered, such as DQB1*0302, which is positively associated with T1DM, or DQB1*0602, which is negatively associated with T1DM (Table 20-4). The association between HLA and T1DM with the DQB1 alleles therefore would take into account one-half of the HLA-DQ class II molecule (Fig. 20-2), and a functional consequence that controls T1DM development needs to be identified. The same reasoning is applicable to the many different known alleles of DQA1. It is noted in this respect that most Japanese T1DM patients are DQA1*0301 positive, the same as Caucasians.⁹⁵ Second, the Asp-Arg model⁸⁹ would represent the other approach in which amino acid polymorphisms in the DQB1 and DQA1 alleles, respectively, are used to estimate risk. As indicated, this approach is not sufficient to explain T1DM susceptibility. Third, disease susceptibility is estimated based on the DQB1-DQA1 haplotype. The hypothesis is that the entire DQ class II molecule is more predictive of susceptibility to T1DM than either DQ chain alone or single amino acids such as DQB1 non-Asp57 and DQA Arg52. Analyses of population-based families suggest that the order of fit is DQB-DQA > DQB1 > DQB1-Asp57/DQA1 Arg52.^{68,69} There is no evidence that DQB1*0302 was more strongly associated with T1DM than DQA1*0301. In conclusion, T1DM susceptibility and protection are probably controlled by the expression and function of HLA-DQ class II molecules. The mechanisms may be specific peptide binding to the groove illustrated in Fig. 20-5 and selective initiation of an immune response, perhaps to a T1DM-associated autoantigen such as GAD-65, insulin, or IA-2.

The DQB-DQA molecules that may be formed following either *cis*- or *trans*-complementation are illustrated in Fig. 20-3. Functional studies on peptide loading, binding, and presentation to T lymphocytes are in progress to explain the mechanisms by which

HLA-DQ may control T1DM.^{71,99} It has been shown that DQB-DQA heterodimers are able to present peptides of GAD-65 and insulin, the two major autoantigens in T1DM (discussed later). In humans, T-cell responses restricted by HLA-DQ or HLA-DR and dependent on antigen presentation of GAD-65 have been reported.^{99,100}

The sequencing of the HLA-DR-DQ-DP region (Fig. 20-4) has identified a number of novel genes. Their products have been shown to fulfill distinct mechanisms in the antigen-presentation pathways for both class I and II molecules. The region between DQ and DR is sufficiently large to harbor yet other genes. It is therefore still possible that the DQ-DR association with T1DM is secondary to yet other genetic factor(s). Sequence analysis of the DQB1*0302 and DQB1*0301 promoter regions has indicated base pair differences that may control rates of transcription of these molecules.⁶⁰ Such upstream sequences are important to explore because they often control tissue-specific expression. Sequence analysis combined with functional analyses should make it possible to map the location of putative susceptibility gene loci by comparing absolute RRs with the location on the chromosome. Given the extent or the size of the HLA-D region, it cannot be excluded that genetic elements other than those coding for HLA class II proteins may confer susceptibility to disease. This is exemplified by the observation that congenital severe combined immunodeficiency is linked to flanking sequences that control gene expression.¹⁰¹

The HLA class II molecules restrict the immune response to external antigens, and they are thought to control the development of nonresponsiveness or tolerance to self-molecules.⁷⁷ Nonresponsiveness to self may primarily be maintained by T-cytotoxic, regulatory, or suppressor cells. These cells are also dependent on antigens presented by class II molecules. It is conceivable that HLA association to disease, including T1DM, is primarily related to mechanisms of protection or nonsusceptibility.⁷⁹ Studies on the ability of antigen-presenting cells (APCs) to stimulate T-cell proliferation in response to β cells¹⁰² or specific β -cell autoantigens such as insulin, IA-2, or GAD-65 may help to resolve these issues.

DR3 specificity is most commonly found in association with DR4 because HLA-DR3/4 heterozygotes may comprise as many as 35–45% of T1DM children or young adults.^{67,103} As pointed out previously, the DQ locus on DR3-containing chromosomes varies less than the DQ associated with DR4. It is therefore likely that a function of DR3-DQ2 class II molecules influences the pathogenesis of T1DM. In patients with T1DM, DR3 has been associated with low immune responsiveness to insulin,¹⁰⁴ as well as to mumps and coxsackievirus B4, but not to varicella-zoster or purified protein derivative (PPD) of tuberculin.^{105,106} In contrast, DR4 was associated with an increased T-cell proliferative response to mumps and coxsackievirus antigens.

These studies need to be confirmed because it is unclear why the two DR types, which are both strongly associated with T1DM, would show opposite effects on antigen-specific T-cell proliferation. One possibility is that DR3, DR4, or both are only in linkage disequilibrium with DQ and that the observations regarding mumps and coxsackievirus are not predictive of T1DM. Another is that DR3 is associated with attenuated immune function, such as removal of immune complexes, which promotes DR4-mediated stimulation of autoreactive T cells and autoantibodies. It is possible that such reactions would either initiate or potentiate an already established immune reaction toward the β cells. It should also be kept in mind that the HLA class II molecules control both T-helper and T-regulatory cell mechanisms.¹⁰⁷ Whether the development of T1DM is dependent on helper cells, regulatory cells, or both is un-

known. The former would seem to require an active immunization with an immunogen from the islets directly or a mimicking β -cell antigen to give rise to an immune response toward the β cells. The latter scenario has been invoked based on evidence that there are sequence homologies between GAD-65 and coxsackie B4.¹⁰⁸ GAD-65 has also been used in experiments to test whether HLA class II molecules control the development of T1DM by their ability to present GAD-65 peptides.^{109,110} In addition, investigations with GAD-65, coxsackie B4, and peptides of each protein allow a test of the hypothesis that molecular mimicry may initiate autoimmunity but only in certain HLA-susceptible individuals.

The particular proneness to develop T1DM among HLA-DR3/4-DQ-2/8 positive individuals remains to be explained. It has been speculated¹¹¹ that the formation of *trans*-complementation HLA class II molecules explains the markedly increased risk of DR3-DQ2 and DR4-DQ8 together (Fig. 20-3). *Trans*-complementation HLA-DQ molecules have been demonstrated in DR3/4-positive IDDM patients.¹¹¹ The role of such class II molecules in cell-cell interaction, antigen processing, and presentation is currently not known. The specific amino acid sequence of the α and β chains may determine in part their ability to form such heterodimers.⁷⁹ Reagents such as monoclonal antibodies¹¹² or antibodies against synthetic peptides,¹¹³ which are able to detect α and β chains of defined specificities, should help clarify the presence and functional capacity of *cis*- and *trans*-complementation molecules in the human immune response.

One possible mechanism to explain cell-specific autoimmunity would be if the target cell was able to express HLA class II molecules. It is conceivable that cell-specific self-antigens could be presented by the target cell itself and could thereby induce an immune response by activating appropriate T lymphocytes. Class II molecules are rarely expressed on nonlymphoid cells. The first evidence of aberrant expression was obtained in skin cells of mice with graft-versus-host disease. In organ-specific autoimmunity, thyroid cells may express class II molecules in thyroiditis-affected glands.¹¹⁴ *In vitro* studies indicated that it was possible to induce class II expression by mitogens¹¹⁵ or cytokines such as interleukin-1 (IL-1), IL-2, interferon- γ (INF- γ), or tumor necrosis factor (TNF) in both thyroid and islet cells.¹¹⁶ Studies in the NOD mouse and the BB rat failed to reveal class II expression on β cells, but such expression was found on endothelial cells and on infiltrating mononuclear cells.¹¹⁷ The detection of class II-positive β cells in a newly diagnosed patient evaluated by immunocytochemistry¹¹⁸ could not be confirmed in other patients.¹² Aberrant class II expression in human β cells¹¹⁸ has also been questioned by the observation that at least some of the islet class II-positive cells are macrophages containing insulin granules due to phagocytosis of β cells that have undergone apoptosis.^{119,120}

The hypothesis of aberrant expression of class II molecules inducing an autoimmune response was also tested in transgenic mice.^{121,122} In these experiments the class II molecule α - and β -chain genes have been inserted into the mouse genome and expressed in the β cell under control of the insulin gene promoter. This aberrant class II expression does not induce insulinitis. Hyperglycemia may develop, due presumably to interference with insulin biosynthesis.^{121,122} Furthermore, islet β cells expressing class II molecules isolated from the pancreas of transgenic mice were unable to present antigen to induce specific T-lymphocyte responses.¹²³ These studies suggest that aberrant class II antigen expression on β cells *per se* does not induce an inflammatory response. In contrast, expression of the IFN- γ gene under control of

the insulin gene promoter was associated with the development of both hyperglycemia and insulinitis.¹²¹ Similarly, transgenic mice expressing IFN- α in the β cells develop insulinitis and diabetes, indicating the possible importance of this cytokine in a pathogenetic immune response.¹²⁴ IL-1 β transgenic mice did not develop insulinitis or diabetes, similar to IL-10-producing transgenic mice.¹²⁵ A backcross of the IL-10 transgene onto NOD mice resulted in an acceleration of the T1DM. Therefore, current experimental evidence does not support the hypothesis that aberrant class II expression on target β cells can initiate insulinitis, but it does support the possibility that the expression of class I and II molecules within the islet is influenced by the presence of cytokines.

The process of generating endogenous immunogenic peptides is poorly understood. Several genes clustered in the MHC class II region (Fig. 20-4) are thought to be involved in the generation and transport of endogenous immunogenic peptides for MHC class I molecules.¹²⁶ The transporter-associated peptide genes TAP 1 and TAP 2, which are located between HLA-DP and HLA-DQ, encode the heterodimeric protein complex responsible for transporting endogenous peptides from the cytosol to the lumen of the endoplasmic reticulum (ER). Two other genes, LMP 2 and LMP 7, also located between HLA-DP and HLA-DQ, interdigitating between the TAP 1 and TAP 2 genes, are believed to be involved in the generation of peptides in the cytosol. These proteasome subunits are present in both cytoplasm and nucleus and generate, through multiple protease specificities, a great diversity of short peptides of different lengths.¹²⁷ The gene products of these four genes are members of the adenosine triphosphate (ATP)-binding cassette (ABC) super family. The proteasome subunits LMP 2 and LMP 7 are not essential for the generation of antigenic peptides, because cell lines deficient in these subunits present peptides to T cells.¹²⁸

Each TAP gene encodes an approximately 75-kd IFN- γ -inducible protein. The functional transporter consists of either a heterodimer or some combination of the TAP 1 and TAP 2 proteins.¹²⁹ In TAP 1, two polymorphic residues at position 333 (Ile for Val) and 637 (Asp for Gly), generate four possible alleles. TAP 1A is the most common allele followed by TAP 1B and TAP 1C. In TAP 2, four polymorphic residues at position 379 (Ile for Val), 565 (Ala for Thr), 665 (Ala for Thr), and 687 (stop codon for Gln) allow the formation of eight possible alleles. TAP 2A is the most common followed by TAP 2B and TAP 2C. The TAP-2 allele 0101 was positively associated, and TAP-0201 negatively associated, with T1DM, whereas TAP-1 did not show any significant association.⁶⁹ However, the TAP allele association with T1DM was lost when HLA-DR-DQ-matched patients and controls were compared,^{130,131} and therefore the effect of the TAP gene was most likely due to linkage disequilibrium.

Association with Other Genes on Chromosome 6

The genes for TNF- α and TNF- β are also located in the MHC region (Fig. 20-4). Both genes have polymorphisms associated with T1DM.¹³² Although TNF- β alleles differ between HLA-DR-matched Caucasian T1DM patients and controls,¹³³ this was not found in North Indian Asians, suggesting that TNF- β does not directly predispose to T1DM.¹³² The genes for heat shock protein (HSP) are also located in the MHC region. The increased frequency of an HSP70-2 9.5-kb Pst fragment among T1DM patients compared with controls was explained by linkage disequilibrium with DR3.¹³⁴ Consistent with this conclusion is the observation that Japanese T1DM patients do not show an association with HSP70.¹³⁵

The properdin factor B (Bf) F1 allele has been reported to be increased among T1DM patients compared with controls, but only among 5–25% of the patients.¹³⁶ BfF1 was not increased among DR3/4 T1DM patients compared with DR3/4 controls, suggesting that the Bf association was secondary to the DR association.¹³⁷ The two complement genes C4A and C4B also showed associations with T1DM.¹³⁸ The data in one study suggested that the association of C4A3 and C4B3 was independent of the HLA-DR association.¹³⁷ However, the risk conferred by the C4 genes is lower than that conferred by the DR or DQ class II genes.

Association and Linkage with Chromosome 11

Sequence analysis of the human insulin gene revealed the presence of upstream (5'-flanking) variable-number tandem repeat (VNTR) sequences.¹³⁹ Although the function of VNTRs is unknown, numerous studies have been carried out to test whether the large compared with small repeat sequences were associated with T1- or T2DM.¹³⁹ Although an association with T2DM was eventually excluded, the T1DM association was reproducible in several ethnic groups.¹⁴⁰ Exploration of other polymorphic sites in and around the insulin gene also revealed an association but no genetic linkage.^{139,140} Although the T1DM VNTR was transmitted preferentially to DR4-positive diabetic offspring in multiplex families,¹⁴¹ there was no difference in frequency among DR4-positive and -negative patients, suggesting that the susceptibility conferred by the insulin gene is independent and nonsynergistic with HLA susceptibility.¹⁴¹ Additional insulin gene polymorphisms have been detected by sequencing patient and control haplotypes.^{140,142} Polymorphisms in the 5'-flanking region of the insulin gene¹⁴² were not found to be directly associated with T1DM because these markers were present on haplotypes that were either associated or not with T1DM.¹⁴⁰ It was suggested that the size variation of the VNTR at the 5' end of the insulin gene could have a direct effect on the insulin gene regulation.¹⁴³ The short class I VNTR alleles (26–63 repeats) predispose to T1DM, whereas class III alleles (140–210 repeats) have a dominant protective effect. When expression of insulin in human fetal thymus was examined, it was found that class III VNTR alleles were associated with two- to threefold higher proinsulin mRNA levels than class I.^{144,145} It was suggested that higher levels of thymic insulin expression may facilitate immune tolerance induction as a mechanism for the dominant protective effect of class III alleles.

Association with Immunoglobulin Genes

The mechanisms by which human immunoglobulins are genetically encoded and synthesized are known.¹⁴⁶ Prior to detailed analyses of the molecular genetics of the immunoglobulin gene heavy and light chains, it was tested whether certain allotypes of the immunoglobulin genes such as Km (light chain) and Gm (heavy chain) were associated with T1DM or linked to the disease in family studies (Table 20-5). The results have been controversial.^{147,148} The allotype Gm(I) was reported to be increased among DR3/4 patients compared with controls.¹⁴⁹ An interaction between immunoglobulin allotypes and T-cell receptor genes was also reported,¹⁵⁰ and in a sib-pair analysis there was an HLA-dependent increase in sharing Gm phenotypes,¹⁵¹ although other studies failed to detect linkage.¹⁵²

Taken together, the data suggest that although Gm and Km allotypes do not provide direct disease susceptibility, they may interact with sex, age, and/or the HLA genes to influence susceptibility.

TABLE 20-5. Candidate Type 1 Diabetes Susceptibility Loci Identified by Linkage Analysis

Locus	Chromosome	Candidate Genes or Microsatellites
IDDM1	6p21.3	HLA (DQA1, DQB1, DRB1)
IDDM2	11p15.5	INS-VNTR, TH
IDDM3	15q26	D15S107
IDDM4	11q13.3	FGF3, D11S1917, MDU1, ZFM1, RT6, ICE, CD3, etc
IDDM5	6q25	ESR, a046Xa9, MnSOD
IDDM6	18q12-q21	D18S487, D18S64, JK (Kidd locus)
IDDM7	2q31-33	D2S152, D2S326, GAD1
IDDM8	6q25-27	D6S281, D6S264, D6S446
IDDM9	3q21-25	D3S1303
IDDM10	10p11-q11	D10S193, D10S208, GAD2
IDDM11	14q24.3-q31	D14S67
IDDM12	2q33	CTLA-4, CD28
IDDM13	2q34	D2S137, D2S164, IGFBP2, IGFBP5
IDDM14	Not assigned	Not assigned
IDDM15	6q21	D6S283, D6S434, D6S1580

It should be kept in mind that the Gm system is a marker for the constant region genes and that variable (V) region gene markers, which are now available as cloned gene probes, may be more likely to detect hypothetical polymorphisms associated with T1DM or other autoimmune disorders. The possible genetic control of antibody formation by HLA also needs to be analyzed, because it was reported that the immunoglobulin allotype association was observed in HLA-DR4 positive individuals only.

Association with T-Cell Receptor Genes

The T-cell receptor (TCR) is a heterodimer composed of an α and a β chain (Fig. 20-2). The genes for these two chains have been cloned and sequenced; the β chain is coded for on chromosome 7. Two additional genes for T-cell receptor chains, δ and γ , have recently been described. The TCR expressed on helper CD4 T lymphocytes recognizes foreign peptides in the context of HLA class II molecules, whereas cytotoxic CD8 T lymphocytes have TCR that recognizes foreign peptides in the context of HLA class I molecules (for review, see ref. 153).

The mechanisms by which TCR is formed or expressed in response to external or internal (autoantigen) antigens are not known. In autoimmunity, is it possible that the TCR involved in activities of the different types of T cells is derived from a limited number of specific variable (V) α - or β -gene sequences? Studies in the spontaneously diabetic NOD mouse and BB rat have so far failed to detect a preferential usage of V β or V α genes.¹⁵⁴ A preferential use of V β was reported in experimental allergic encephalomyelitis (EAE).¹⁵⁵ This information is of particular interest because monoclonal antibodies against this specific TCR may be used to specifically deplete T lymphocytes expressing this particular TCR and thereby inhibit an immune response and prevent autoimmune disease.¹⁵⁵ Given the complexity of the TCR genes and their transcription and translation to form TCR, it is not surprising that current results on disease association in different ethnic populations are contradictory. Early reports showed that the heterozygotes of the TCR- β Bgl II RFLP were increased among T1DM patients compared with controls.¹⁵⁶ Later studies failed to detect this association.¹⁵⁷ There was no linkage between T1DM and TCR-C β .¹⁵⁸ There is one report suggesting that the TCR-C β association is de-

pendent on the immunoglobulin heavy-chain region genes, as the distribution of TCR-C β differs between patients with G2m(23+) or G2m(23-), as well as between G3m(5+) and G3m(5-).¹⁵⁰ Recently, a polymorphism in the TCR-C λ but not TCR-V λ gene was associated with T1DM, in particular among DR3 and DR4 individuals.¹⁵⁹ In further studies to determine the possible role of autoantigen-specific TCR in the development of T1DM, the crystal structure of the NOD mouse I-Ag7 HLA-DQ homolog was determined as a complex with a high-affinity peptide from GAD.⁸⁵ I-Ag7 had a wide peptide-binding groove (Fig. 20-5B), which may account for disease-associated peptide binding. Similar results have recently been reported for HLA-DQ8 molecules and may be of importance in understanding the role of peptide binding in T1DM pathogenesis.¹⁶⁰

Association with Other Genetic Markers from Genome Scanning

Other genetic markers for T1DM (Table 20-5) have been obtained by recent human genome scanning studies to support the previous observation¹³⁹ that other genetic factors may contribute to the risk for T1DM. The development of simple sequence repeat (SSR) markers to map the human genome made it possible to identify linkage between SSR markers and T1DM.^{63,161,162} These studies required knowledge of the inheritance of T1DM such that genetic linkage was calculated from the simultaneous inheritance of SSR markers in affected siblings. DNA collection available to investigators throughout the world through the Human Biological Data Interchange (HBDI)^{163,164} and from the British Diabetic Association (BDA) made it possible to identify several T1DM risk loci.^{63,161,165} There may be as many as 14–18 such risk loci, although the number reproducible in all populations is controversial.^{63,166}

HLA and insulin VNTR are estimated to contribute to about 40% and 10%, respectively, of familial clustering of T1DM. Other contributing genes are therefore expected. Among these, CTLA-4 on chromosome 2 has been reproduced in several ethnic groups.^{167,168} Polymorphisms in the coding as well as noncoding regions of the CTLA-4 gene are associated with autoimmune diseases such as Graves' disease as well as T1DM.¹⁶⁸ The association between CTLA-4 and T1DM in a case-control study indicated that long (AT) n repeats at the 3' end of the gene are associated with T1DM.¹⁶⁹ The mechanism explaining this association remains to be clarified. One possibility is that the CTLA-4 polymorphism affects the survival of autoreactive regulatory T cells. Although HLA seems necessary, it is clearly not sufficient for the appearance of T1DM; one or several contributing genes may affect the pathogenetic process and age at onset. The possibility cannot be excluded, however, that other genetic factors important to β -cell function may contribute to T1DM risk. It is predicted that high-throughput genetic typing methods such as analysis of single nucleotide polymorphisms (SNP) will provide novel means by which large numbers of patients and controls can be used to improve the current T1DM genetic map.

IMMUNE ASPECTS

Autoantibodies

Autoantibodies reactive with antigens contained in pancreatic islet cells are common in T1DM (Table 20-6). Antibodies reactive against islet cell antigens (islet cell antibodies [ICAs]) were first

TABLE 20-6. Islet cell autoantigens of Insulin-Dependent Diabetes Mellitus

Autoantigen	Characteristics
Sialoglycolipid	Target of ICA in humans, GM2-1, non-beta-cell specific
Glutamate decarboxylase	Target of 64-kd antigen/GAD antibody in humans and animal models of IDD, two forms (GAD65 and 67), cellular immune antigen, synaptic like microvesicle protein, disease-modifying antigen
Insulin	Target of IAA in humans and non-obese diabetic (NOD) mice, cellular immune antigen, disease-modifying antigen
Insulin receptor	Target of autoantibodies in humans determined by bioassay
38 kd	Target of 38-kd antigen in humans, induced by cytomegalovirus, localized to insulin secretory granules, cellular immune antigen, multiple antigens of this molecular mass?
Bovine serum albumin	Target of BSA antibody, antigen in humans and animal models of IDD, contains ABBOS peptide, has molecular mimic in beta cell p69 protein (PM-1), disease-modifying antigen
Glucose transporter	Target of autoantibodies in humans, inhibit glucose stimulation. Glut-2 directed?
hsp 65	Target of autoantibodies and cellular immunity in NOD mice, disease-modifying antigen, contains p277 peptide.
Carboxypeptidase H	Target of autoantibodies in humans, identified by immunoscreening of islet cDNA, insulin secretory granule protein
52 kd	Target of autoantibodies in humans and NOD mice, molecular mimic with rubella virus
ICA12/ICA512	Target of autoantibodies in humans, identified by immunoscreening of islet cDNA, 5123 homology to CD45
150 kd	Target of autoantibodies in humans, beta-cell specific, membrane associated
RIN polar	Target of autoantibodies in humans and NOD mice, present on insulinoma cells

described in 1974 and provided strong evidence for an autoimmune etiology and pathogenesis for T1DM. The initial description of ICA has been followed by a large number of reports describing the presence of antibodies reactive with a variety of islet cell components. These include antibodies to insulin, proinsulin, GAD, carboxypeptidase H, a sialoglycolipid, and several other incompletely defined antigens of different molecular weights: 37, 38, 52, 64, 69, and 150 kd.¹⁷⁰ Most of these antibodies occur with high prevalence in newly diagnosed T1DM subjects and prior to clinical appearance of diabetes. Their presence is useful in detecting β -cell autoimmunity and in assessing the risk of subsequent clinical T1DM in genetically susceptible individuals. However, the relationships among the various islet cell autoantibodies, β -cell autoimmunity, and eventual clinical T1DM is very complex and still not fully characterized or understood. Of all the autoantibodies described in T1DM, four are clinically most useful: ICA, IAA, GADA, and IA-2A.

When ICAs were first discovered in 1974, it was felt that all individuals with ICAs would eventually develop clinical T1DM. This is not the case, and recent extensive investigation in this area has revealed considerable complexity. When ICAs are detected in non-diabetic individuals identified because of other autoimmune diseases besides diabetes, the risk of subsequent clinical T1DM is less than when ICAs occur in relatives of T1DM patients.¹⁷¹ Similarly, ICA-positive individuals from the general population without a family history of T1DM have a much lower risk of T1DM than ICA-positive relatives of T1DM patients.^{172,173} In fact, ICAs can occur in people with protective HLA haplotypes, and in these individuals subsequent clinical T1DM is unusual.^{174,175} Several subsets of ICAs have been identified with varying risks of T1DM. A subset termed **restrictive**, because the staining pattern is restricted to the β cells and does not stain mouse pancreas, is less predictive of subsequent T1DM than ICAs reactive with all islet endocrine cells and with mouse pancreas.¹⁷⁴ Similarly, ICA binding that is displaceable with GAD or that gives a granular staining pattern is less predictive of subsequent T1DM than conventional ICA.^{170,176}

Insulin autoantibodies have become equally complex. In relatives of T1DM patients, the presence of IAAs in addition to ICAs greatly increases the risk of subsequent clinical T1DM compared with ICAs alone, but relatives with IAAs without ICAs have only a minimally increased risk of clinical T1DM.¹⁷⁷ Certain drugs such as methimazole and penicillamine can induce IAAs, but these subjects develop hypoglycemia, not T1DM. Some viral infections can induce IAAs of the IgM subclass, which are also unrelated to T1DM.¹⁷⁸ An international workshop revealed that IAAs measured by fluid-phase assays were predictive of subsequent clinical T1DM, whereas IAAs measured by solid-phase enzyme-linked immunosorbent assay (ELISA) were not.¹⁷⁹ It has not been resolved whether this is due to the two assay formats measuring antibodies of different affinities or to antibodies directed against different epitopes on the insulin molecule, but only fluid-phase IAA assays should be used to assess the risk of T1DM.

In 1990 Baekkeskov and colleagues¹⁸⁰ reported that the 64K autoantigen recognized by antibodies from T1DM patients was GAD. A wealth of data regarding 64K antigens and antibodies to these antigens in T1DM obtained over the last few years has revealed that this area is as complex as for ICAs and IAAs. GAD exists in at least two major isoforms, GAD-65 and GAD-67. Their respective distributions in β cells and neural tissue vary between species, and although antibodies to both isoforms can occur, antibodies to GAD-65 are predominantly associated with T1DM in humans.¹⁸¹ Several assay formats including fluid-phase, ELISA, and enzymatic assays have been developed, and an international workshop demonstrated, as for IAAs, marked differences related to methodology. In general, fluid-phase measurements of GAD-65 antibodies were most closely correlated with T1DM.¹⁸² GAD autoantibodies are very common in the rare neurologic disorder, stiff-man syndrome, and only a small percentage of these patients develop T1DM. Furthermore, the GAD autoantibodies in T1DM and stiff-man syndrome appear to differ in their ability to inhibit GAD enzymatic activity and in recognizing antigen in Western blot assays.¹⁸³ As discussed previously, ICAs that are displaceable with GAD are surprisingly less associated with T1DM than ICAs not recognizing GAD.¹⁷⁰ Recent data have also revealed that antibodies from T1DM subjects binding to 64K islet antigens include antibodies to antigens other than GAD. Some investigators have identified antibodies to HSP65 in T1DM,¹⁸⁴ but others have not,¹⁸⁵ so this remains a controversial area.

The maturation of the humoral response to GAD epitopes sequentially from birth to diabetes onset or current follow-up in GAD antibody (GADA)+ offspring of parents with diabetes was examined recently in the German BABYDIAB Study.²⁸ Antibodies were measured against GAD-65, GAD-67, and GAD-65/67 chimeras by radiobinding assay. In 28 of 29 offspring, the first GADA contained reactivity against epitopes within GAD-65 residues 96-444, suggesting that the middle GAD-65 region is a primary target of GAD humoral autoimmunity. Subsequent GADA epitope spreading was frequent, and spreading was mostly to NH2-terminal GAD-65 epitopes. In two offspring, spreading to new epitopes was found when antibody titers to GAD-65 and early epitopes were declining, suggesting determinant-specific regulation of the humoral response. None of the GADA reactivities or any changes in reactivity over time were specifically associated with diabetes onset. These findings suggested that the humoral autoimmune response to GAD found in childhood is dynamic, is initially against epitopes within the middle portion of GAD-65, and spreads to epitopes in other regions of GAD-65 and GAD-67. Hampe and colleagues¹⁸⁶ showed that recognition of epitopes by GAD-65 Ab in T1DM is different from that in non-T1DM, GAD-65 Ab-positive individuals. Further studies demonstrated that the N-terminal part is essential for full antibody binding to GAD-65, in particular to the middle epitope. It was suggested that T1DM is associated with restricted GAD-65Ab epitope specificity, and the evolution of GAD-65 autoantibodies in T1DM includes reactivity to a non-human GAD-65 N-terminal end conformation. Progression toward T1DM is, however, associated with a maturation of the immune response toward human GAD-65 autoreactivity.¹⁸⁷⁻¹⁸⁹

In very elegant experiments, Christie and colleagues¹⁹⁰ have demonstrated antibodies in T1DM to a 64-kD islet protein distinct from known isoforms of HSP or GAD. Antibodies recognizing a 37-kD tryptic fragment of this non-GAD 64-kD antigen were more predictive of T1DM than GAD autoantibodies.¹⁹⁰ These autoantibodies are now known as ICA512 or IA-2 (directed to the neuroendocrine protein insulinoma-associated protein 2, a member of the protein tyrosine phosphatase family).^{191,192} Kawasaki and coworkers¹⁹³ have examined the overlapping specificities and antigenic epitopes of autoantibodies to IA-2 and phosphatase homolog in granules of insulinoma (phogrin) and determined whether intramolecular epitope spreading occurs during the development of diabetic autoimmunity. IA-2 autoantibodies and phogrin autoantibodies were detected in 65-70% of patients with new-onset T1DM and 60-65% of prediabetic relatives of patients with T1DM. Binding and competition analysis using multiple chimeric IA-2/phogrin constructs demonstrated that a major unique epitope for IA-2 autoantibodies is localized to amino acids 762-887. These studies highlighted the complexity of autoantibody recognition of IA-2/phogrin. Park and colleagues⁵³ investigated whether alternative splicing could affect humoral autoreactivity to the molecule. Radioimmuno-precipitation assays for IA-2/ICA512 autoantibodies were developed with the widely used ICA512.bdc construct (which has exon 13 deleted) and a series of full-length and modified ICA512/IA-2 molecules. The assays showed that ICA512.bdc and ICA512 604-979 gave the best discrimination between diabetic and control sera. With ICA512 604-979, a somewhat greater proportion of patients expressing antibodies were detected than with ICA512.bdc in the groups studied (70.5% vs. 63.2% of prediabetic/new-onset patients and 25.0% vs. 13.9% of patients with diabetes >20 years). They concluded that important epitopes lie within the exon 13 region and others can be generated by the alternative splicing.

The combinatorial Islet Autoantibody Workshop assessed the ability of individual autoantibody (ab) assays and their use in combination to discriminate between T1DM and control sera.¹⁹⁴ Coded aliquots of sera were measured in a total of 119 assays by 49 participating laboratories in 17 countries. The sera were from 51 patients with new-onset T1DM and 101 healthy control subjects with no family history of diabetes. There were no significant differences in sensitivity among 19 radioimmunoassays (RIAs) for IA-2 autoantibodies (ICA 512) using different constructs that included the intracellular portion of the molecule (mean sensitivity 73%). Among GAD autoantibody assays that achieved sensitivity >70%, 26 were RIAs and 1 was an ELISA. When the sera were ranked according to their autoantibody levels, the concordance for IAAs in different laboratories was markedly less than for IA-2A and GADA. Using a combination of autoantibody assays, several laboratories achieved excellent discrimination between diabetic and control sera (sensitivity up to 80% with a false-positive rate of 0%). A variety of strategies for combining information from different assays were successful (e.g., those including and excluding ICA), and no one strategy emerged as clearly superior.¹⁹⁴

The relationships between genetic markers and disease-associated autoantibodies were studied in an unselected population of 701 siblings of children with T1DM, and the predictive characteristics of these markers over a period of 9 years were determined.¹⁹⁵ Increased prevalences of all the antibodies were closely associated with HLA identity to the index case, the DR4 and DQB1*0302 alleles, the DR3/4 phenotype, and the DQB1*02/0302 genotype. GADAs were also associated with the DR3 and DQB1*02 alleles, and siblings carrying the protective DR2 and DQB1*0602-3 alleles were characterized by lower frequencies of ICAs, IA-2A, and GADA. A combination of the genetic markers and autoantibodies increased the positive predictive values of all autoantibodies substantially, which may have clinical implications when evaluating the risk of developing T1DM at the individual level or when recruiting high-risk individuals for intervention trials.¹⁹⁵ However, because such combinations also resulted in reduced sensitivity, autoantibodies alone rather than in combination with genetic markers are recommended for first-line screening in siblings. Finally, not all siblings with a broad humoral autoimmune response or high-risk genetic markers present with T1DM, and some with a low genetic risk and weak initial signs of humoral autoimmunity may progress to disease. Lindberg and coworkers^{196,197} tested for various islet autoantibodies in cord blood sera from controls and children who developed T1DM between 10 months and 14.9 years of age. An increased frequency of cord blood islet autoantibodies suggested that the T1DM process could already be initiated *in utero*.^{196,197}

Although autoantibodies could damage β cells by antibody-dependent complement cytotoxicity or by targeting natural killer cells to β -cell antigens, transfer of T1DM in the animal models requires T cells, and consequently a major direct role for antibodies in causing the β -cell damage of T1DM is unlikely. The findings that intrathymic or intravenous administration of GAD can prevent T1DM in the NOD mouse^{198,199} and that T cells reactive with insulin can transfer T1DM in the NOD mouse model²⁰⁰ suggest important direct roles for GAD and insulin in T1DM. The 9–23-amino acid region of the insulin B chain (B9–23) is a dominant epitope recognized by pathogenic T lymphocytes in NOD mice. Maron and colleagues²⁰¹ have shown that oral and nasal administration of insulin or GAD suppresses development of diabetes in the NOD mouse and that this suppression appears secondary to the generation of regulatory T cells that act by secreting anti-

inflammatory cytokines such as IL-4 and transforming growth factor (TGF)- β . They analyzed cytokine patterns associated with mucosal administration of insulin B chain, B-chain peptide 10–24, and GAD peptide 524–543, and derived lines and clones from mucosally treated animals. There was significantly less IFN- γ production in mucosally treated mice associated with increased production of IL-10 and TGF- β . The nature of the antigen appeared to determine cytokine production, as the B chain given either orally or nasally primed for TGF- β responses, whereas mucosally administered B-chain peptide 10–24 primed for IL-10.

Their results supported a role for Th2-type cells (see below for discussion on Th1/Th2 cells) in the regulation of diabetes in NOD mice.²⁰¹ Their further studies showed that neonatal feeding of human insulin or insulin B-chain peptide (10–24) is effective in inhibiting diabetes when given to the NOD mouse,²⁰² and this may have applications in preventing diabetes in high-risk human populations. Studies in the BB rat model also demonstrated that immunization with insulin B chain in the presence of adjuvant can reduce diabetes incidence.²⁰³ The absence of any metabolic effect of B chain and the requirement for adjuvant suggested that this effect is mediated via modulation of the autoimmune response. Alleva and coworkers²⁰⁴ recently described B9–23-specific T-cell responses in peripheral lymphocytes obtained from patients with recent-onset T1DM and from prediabetic subjects at high risk for disease.²⁰⁴ This is the first demonstration of a cellular response to the B9–23 insulin epitope in human T1DM and suggests that the mouse and human diseases have strikingly similar autoantigenic targets, a feature that should facilitate development of antigen-based therapeutics.

Cellular Immune Response and Cytokines

T1DM is thought to result from a T-cell-mediated destruction of the pancreatic β cells. Antigen-specific T-cell activation requires two signals. One is imparted by interaction of the TCR/CD3 complex with the antigen:MHC class II protein complex expressed by APCs. The second signal is provided by cell-bound and secreted costimulatory molecules, which (although not imparting any antigenic specificity) synergize with TCR/CD3 signals in augmenting T-cell activation.^{205,206} Several signal transduction pathways operate as a result of T-cell activation. These include the phospholipase C-1 pathway, the p21^{ras}/RAF kinase (the classical mitogen-activated protein kinase) pathway,²⁰⁷ and the phosphatidylinositol 3'-hydroxykinase/GDP-Rac (the alternative mitogen-activated protein kinase) signaling pathway.²⁰⁸

Coupling to more than one signaling pathway is possible depending on the intensity of the signal generated, the duration of stimulation, and the contribution of costimulatory molecules, which, in turn, affects the duration and outcome of the functional response.^{209,210} Insofar as costimulatory signals determine whether TCR recognition of antigen will lead to activation, apoptosis, or anergy, a role for altered costimulation in the pathogenesis of autoimmune diseases including T1DM^{211,212} has been proposed. Accordingly, manipulation of costimulatory pathways was proposed as a potential strategy for managing autoimmune diseases, including T1DM.²¹²

As part of the insulinitis process, a number of cytokines (soluble polypeptide mediators) are released from the immune cells infiltrating the islet. In addition to their immunologic functions of modulating, amplifying, and directing the immune response, several of the cytokines have been found to have direct effects on the pancre-

atic β cells. The direct effects potentially involved in the pathogenesis of T1DM include inhibition of insulin release, cytotoxicity, and altered antigen expression. The cytokines IL-1, TNF, and IFN have been the most intensively studied. Although there is considerable variability depending on species and possibly other experimental conditions, in general the cytokines mentioned, especially when administered in combination, are cytotoxic to pancreatic β cells.^{213,214} In addition to the impairment of insulin secretion resulting from this cytotoxicity, inhibition of insulin secretion, independent of cytotoxicity, is also observed.^{19,215}

This distinction is potentially very important because it raises the attractive possibility that, especially early in the preclinical period of T1DM, much of the loss of insulin secretory function may be functional in nature and therefore potentially reversible rather than due to irreversible β -cell destruction. Both *in vitro*²¹⁶ and *in vivo*²¹⁷ experimental data suggest that β cells are indeed able to repair after damage. Experiments exposing whole rodent islets of Langerhans to various toxic agents showed that the β cells went through an initial phase of suppressed glucose metabolism and decreased glucose-stimulated insulin release.^{218,219} After they were cultured for 3–7 days in the absence of toxic agent, the surviving β cells were able to regain their function completely. β -cell repair has also been demonstrated after *in vivo* β -cell damage. When pancreatic islets with insulinitis were isolated from female NOD mice at different ages (5–7, 8–11, or 12–13 weeks), the islets showed a deficient glucose-induced insulin release and defective glucose metabolism that progressively worsened with age (Fig. 20-6).^{21,22} The observed β -cell dysfunction showed a close correlation to the severity of the mononuclear cell infiltration and was accompanied by defective glucose metabolism. Both abnormal insulin release and glucose oxidation were completely restored after 1 week of culturing, during which the islet mononuclear cell infiltrate was depleted.^{21,22} In a subsequent series of experiments, treatment of female 12–13-week-old NOD mice with monoclonal antibodies directed against infiltrating T cells markedly reduced the islet inflammatory reaction and restored islet glucose metabolism, when the islets were isolated after a 10-day period.^{21,22,220}

These data suggest that in prediabetic NOD mice, a population of suppressed and/or partially damaged (but still viable) β cells exists. If the immune assault is arrested, either by removing the islets from the *in vivo* environment^{21,22} or by eliminating the invading T cells with specific monoclonal antibodies,²²⁰ these β cells can use repair mechanisms and regain normal function. Anti-CD3 monoclonal antibodies suppress immune responses by transient T-cell depletion and antigenic modulation of the CD3/TCR complex, and anti-CD3 treatment of adult NOD mice with recent onset diabetes can restore normoglycemia.²²¹

Cytokines also cause alterations in the β -cell expression of many other proteins besides insulin. Some proteins are stimulated, whereas others are inhibited. IFN- γ commonly stimulates MHC class I antigen expression in many cell types and may be responsible for the increased class I expression on islet β cells in T1DM, as treatment of NOD mice with antibodies to IFN- γ prevents MHC class I expression in the insulinitis lesion.²²² An important role for IFN- α in T1DM is suggested by transgenic mice expressing IFN- α in their pancreatic β cells; these mice develop insulinitis, lymphocyte autoimmune destruction of their islet β cells, and T1DM.²²³ Gel electrophoresis has shown that cultured islets exposed to IL-1 decrease the expression of many proteins and increase the expression of others.²²⁴ IL-1 inhibits the expression of GAD (unpublished observations) and stimulates the expression of islet ganglioside,²²⁵ HSP70,^{226,227} hemoxygenase,²²⁶ and superoxide dismutase.²²⁸ It has been proposed that some of these proteins, especially HSP70, hemoxygenase, and superoxide dismutase, may be protective to the β cell and/or aid in recovery of the β cell from damage.²²⁹

Cytokines are recognized to be an important component of the immune mechanism determining whether the immune response of CD4+ T cells to an antigen is primarily cellular (Th1) or humoral (Th2). T-helper cells differentiate into at least two major subtypes, Th1 and Th2, which are functionally distinct and distinguished by different cytokine secretion patterns. Th1 cells produce IL-2, IFN- γ , and TNF- β , whereas Th2 cells produce IL-4, IL-5, and IL-10. Functionally Th1 cells and their respective cytokines are involved in delayed-type hypersensitivity responses, macrophage

FIGURE 20-6. Insulin release (A) and glucose oxidation (B) from isolated pancreatic islets of 12-week-old female NOD mice or 12-week old NMRI mice. Both insulin release and glucose oxidation rates were measured immediately after islet isolation (day 0) and after 7 days in culture (day 7). (Reproduced with permission from Eizirik et al.²²⁹)

and cytotoxic T-cell activation, and weak B-lymphocyte activation mediating immunoglobulin isotype switching to IgG2a and IgG3.²³⁰ In contrast, Th2 cells and their respective cytokines strongly activate B lymphocytes, stimulate humoral immune responses, and mediate isotype switching to IgG4 and IgE in humans.^{231,232} Although Th1 and Th2 lymphocytes can each elicit memory IgG1 responses via different signals,²³³ Th1 and Th2 responses are largely mutually inhibitory; Th2 cytokines suppress Th1 responses and *vice versa*. A large number of factors including antigen dose, antigen affinity, route of administration, genetics (including HLA type), and type of APC control differentiation into Th1 vs. Th2 responses.

Considerable data suggest that Th1-type immune responses against islet antigens are associated with progression to clinical T1DM in animals. Transgenic mice expressing the Th1 cytokine IFN- γ in their pancreatic β cells develop insulinitis and diabetes,¹²¹ and in both BB rats and NOD mice monoclonal antibodies against IFN- γ prevent T1DM.^{234,235} Diabetogenic T-cell clones obtained from the NOD mouse are commonly of the Th1-type phenotype, producing IFN- γ but not IL-4²³⁶; GAD-reactive T-cells isolated from NOD mice produce IFN- γ ¹⁹⁷; and insulinitis developing in transplanted islets in diabetes-prone NOD mice demonstrates a high frequency of IFN- γ -producing cells.²³⁷

In contrast, a predominantly Th2-type immune response appears to confer protection against T1DM. Thymocytes from NOD mice have markedly reduced IL-4 production when they are stimulated with TCR monoclonal antibodies, anti-CD3, and concanavalin A (Con A), and administration of IL-4 to prediabetic NOD mice prevents diabetes.^{237,238} In performing islet transplantation experiments in NOD mice and assessing cytokine production by measuring mRNA, Rabinovitch and colleagues²³⁹ also demonstrated that complete Freund's adjuvant (CFA) resulted in decreased expression of IFN- γ in the islets but increased expression of the Th2-type cytokine IL-10. Autoimmune diabetes and insulinitis can be induced in rats by sublethal γ -irradiation and thymectomy and can be prevented by injection of a CD4+ T-cell subset from untreated syngenic rats. These protective cells are of the Th2 phenotype since they produce IL-4 but not IFN- γ when activated *in vitro*.²⁴⁰

The Th1/Th2 paradigm may not be as distinct in humans as in the mouse. For example, in humans both Th1 and Th2 clones produce IL-10.²⁴¹ Nonetheless, there has been correlation of Th1 vs. Th2 with development of human autoimmune diseases.²⁴²⁻²⁴⁴ At diagnosis of human T1DM, IL-4 production by peripheral blood mononuclear cells (PBMCs) is markedly reduced²⁴⁴, and Harrison and coworkers²⁴⁵ demonstrated that preclinical subjects progressing to clinical diabetes had a predominantly cellular reaction to GAD, whereas subjects at less risk of clinical T1DM had a predominantly humoral response to GAD. However, as an antigen, they used GAD-67, which is not a predominant antigen in human diabetes, and their findings are controversial.²⁴⁶

The observations that subjects develop autoantibodies to an increasing number of islet antigens during the preclinical period²⁴⁷ and that multiple islet autoantibodies are much more predictive of future T1DM than a single antibody^{177,248} further support the Th1/Th2 paradigm in humans. Wilson and colleagues²⁴⁹ investigated a series of at-risk non-progressors and T1DM patients (including five identical twin/triplet sets discordant for disease). The diabetic siblings had lower frequencies of CD4-CD8- α 24J α Q+ T cells compared with their nondiabetic sibling. All 56 α 24J α Q+ clones isolated from the diabetic twins/triplets secreted only IFN- γ upon stimulation; in contrast, 76 of 79 clones from the at-risk non-

progressors and normals secreted both IL-4 and IFN- γ . Half of the at-risk non-progressors had high serum levels of IL-4 and IFN- γ . These results support a model for T1DM in which Th1 cell-mediated tissue damage is initially regulated by α 24J α Q+ T cells producing both cytokines; the loss of the secretion of IL-4 is correlated with T1DM.

Th2-type immune responses are preferentially generated by antigen presentation via the gut, and consequently oral tolerance and the resultant protection against autoimmune disease are in some ways analogous to the Th1/Th2 paradigm. Oral tolerance is a term used to describe the tolerance that can be induced by the exogenous administration of antigen to the peripheral immune system via the gut. It is a form of antigen-driven peripheral immune tolerance and appears to involve two main mechanisms that are in part dependent upon the antigen dose. The tolerance induced by lower doses of orally administered antigen appears to be mediated predominantly by active suppression, whereas higher doses tend to induce clonal anergy and/or deletion.²⁵⁰ The active suppression by low doses of oral antigen appears to be mediated by the oral antigen: the antigen generates regulatory T cells that migrate to lymphoid and target organs expressing the antigen administered orally, and confers suppression via the secretion of downregulatory cytokines including IL-4, IL-10, and TGF- β .²⁵¹ Oral immunization with sheep red blood cells induced predominantly Th2-type cells in Peyer's patches, whereas systemic immunization induced predominantly IFN- γ -producing Th1-type cells.²⁵² In animals protected against EAE by the oral administration of myelin basic protein (MBP), mesenteric lymph nodes secrete TGF- β , IL-4, and IL-10, but minimal IFN- γ when stimulated *in vitro* with MBP.²⁵³ Immunohistology of brains from animals affected with EAE, and from orally tolerized and therefore protected animals, further supports the Th1 vs. Th2 paradigm. Brains from unprotected animals showed infiltration with activated mononuclear cells secreting IL-1, IL-2, TNF, and IFN- γ , but not IL-4 and TGF- β . In animals orally tolerized with MBP, the inflammatory infiltrate was markedly reduced, IL-1, IL-2, TNF, and IFN- γ were reduced, and TGF- β and IL-4 were increased.²⁵⁴

It is fairly well established that T1DM is associated with dysregulated humoral and cellular immunity. There is altered production of and response to macrophage-derived and T-cell-derived cytokines, and a shift in T-helper cell differentiation in favor of a pathogenic Th1 pathway. Th1 cytokines may induce islet β -cell destruction directly by apoptosis and by upregulating the expression of select adhesion molecules, and they may facilitate pancreatic homing of autoreactive leukocytes, hence enhancing β -cell destruction. However, more recently, data are also appearing to suggest that in some cases Th2 cells and their cytokines can accelerate β -cell destruction, arguing against the conventional Th1/Th2 paradigm.^{125,255,256} Local production of Th2 cytokines, in particular IL-10, accelerated β -cell destruction by enhancing autoreactive cell infiltration of the pancreas (insulinitis) through modulation of the release of other cytokines and by modulating the microvasculature.²⁵⁵

Both β -cell antigen-specific and nonspecific immune and inflammatory responses may participate in mediating islet β -cell destruction in T1DM.²⁵⁷ The β -cell antigen-specific immune response involves binding of CD8+ T cells to β cells. The T cells specifically recognize β -cell antigen or antigens presented by MHC class I molecules on the β cells. This is followed by activation of the T cells (cytotoxic T cells), which may kill the β cells by receptor (Fas/FasL)-mediated mechanisms or by secretion of cytotoxic molecules (granzymes and perforin).²⁵⁸ The nonspecific im-

mune and inflammatory response that destroys β cells may be mediated by molecules released from activated T cells (both CD4+ and CD8+ T cells) and macrophages, such as proinflammatory cytokines (IL-1, TNF- α , TNF- β , IFN- γ) and free radicals (e.g., superoxide, hydrogen peroxide, the hydroxyl radical, nitric oxide [NO], and peroxynitrite). There is abundant evidence *in vitro* that islet β cells are sensitive to injury mediated by oxygen free radicals²¹² and NO.²⁵⁹ In addition, IL-1, TNF- α , TNF- β , and IFN- γ are cytotoxic to β cells via mechanisms that appear to involve the production of oxygen free radicals or NO (or both) in the β cells themselves.^{212,259} NO production has been demonstrated in pancreatic islets *in situ* in conjunction with T1DM development in BB rats²⁶⁰ and NOD mice.²⁶¹ These findings suggest that both oxygen and nitrogen free radicals contribute to β -cell destruction in the insulinitis lesion of T1DM. It appears that both β -cell antigen-specific CD8+ T cells and antigen-specific as well as antigen-nonspecific CD4+ T cells and macrophages may contribute to β -cell damage in NOD mice and BB rats; however, the precise cytotoxic mechanisms used by these immunologic cells to kill β cells have not been fully elucidated. Moreover, even less is known regarding the mechanisms of β -cell destruction in human T1DM.

Multiple and sometimes conflicting studies have identified a variety of aberrations in the cellular immune response to autoantigens in persons with the disease. Potential explanations for these discrepancies include different techniques or culture conditions, diversity in the populations of patients or controls tested, and differences in autoantigen preparations. T-cell workshops have been organized by the Immunology of Diabetes Society (IDS) with the aim of evaluating assays for detecting autoreactive T cells associated with T1DM.^{262,263}

In the first phase, a series of candidate autoantigens were analyzed by reference laboratories for quality. Subsequently, these preparations, as well as control stimuli, were distributed in a blind fashion to 26 laboratories worldwide, for analysis of T-cell proliferation assays in recent-onset T1DM patients and nondiabetic controls.²⁶² The results using candidate autoantigens indicated that although a few laboratories could distinguish T1DM patients from nondiabetic controls in proliferative responses to individual islet autoantigens, in general, no consistent differences in T-cell proliferation between type 1 patients and controls were identified. The first T-cell workshop on T-cell autoreactivity in T1DM, although confirming that this was a difficult area for interlaboratory investigations, provided insights for future efforts focused on standardizing autoreactive T-cell measurements. The inability to discriminate normal controls from new-onset T1DM patients suggested that measuring proliferative responses in PBMCs represents an incomplete picture of the immune response, perhaps complicated by difficulties in identifying suitable antigens and assays for standardized use.²⁶²

Currently, various assays under trial in the second IDS human T-cell workshop (phase II) are those in which peripheral T cells are used without manipulation, are depleted of naïve T cells, or are enriched for activated (HLA DR+) T cells.²⁶³ In each protocol, subjects included are new-onset T1DM subjects, high-risk autoantibody-positive, first-degree relatives, and matched healthy controls. Measurements include proliferation in the presence or absence of added IL-2, cytokine secretion, and cytokine mRNA quantification. Improved assays may provide new mechanistic insights and improved staging of prediabetes and may eventually allow us to measure the effectiveness of intervention therapies well before the onset of overt disease.²⁶⁴

ENVIRONMENTAL FACTORS

Epidemiology

Various environmental triggers, e.g., certain viruses and dietary factors, have been proposed as initiators of the autoimmune process, leading to the destruction of the pancreatic β cells and consequent T1DM.²⁶⁵ Animal models provide solid evidence that environmental factors can, depending on the experimental conditions, both cause and prevent T1DM, but the relevance of these observations to human T1DM is not clear. However, twin studies, major geographic variations in incidence and prevalence rates, temporal seasonal trends in the incidence, and findings in migrant studies suggest that environmental factors play a crucial role in the development of human T1DM.²⁶⁶ In this section we review the available data dealing with the potential role of environmental factors in the pathogenesis of T1DM.

Perhaps most persuasive are the studies in monozygotic twins. Initial studies had shown that <50% of such twins are concordant for T1DM.^{267,268} Concordance can be the result of genetic and/or environmental similarity, but discordance, especially of this degree, suggests that T1DM, at least in part, is due to nongenetic factors. More recent longitudinal twin studies, with up to 39 years of follow-up from the onset of diabetes in index twins have shown that identical twins may develop diabetes after a prolonged period of discordance and that approximately two-thirds of long-term discordant twins have evidence of persistent β -cell autoimmunity and/or β -cell damage.⁴⁰ This presence of discordance of age of disease presentation also supports, but does not prove, a role for environmental factors. The diagnosis of T1DM follows a seasonal pattern, with incidence peaks in autumn and winter and a nadir in late spring/early summer. This seasonal pattern was first described in 1926,²⁶⁹ has been repeatedly observed by numerous other investigators including ourselves,²⁷⁰ is reversed in the Southern Hemisphere, and is remarkably constant year after year²⁷¹ (Fig. 20-7). Such seasonality has suggested a viral connection, because the general incidence pattern of viral infection in children is similar. A single virus is unlikely to be responsible, because in children the autumn peak is primarily enteroviral infections and the winter peak respiratory viruses. Furthermore, because infection usually results in immunity to subsequent infection by similar viruses for several years, most viruses pass through a given community with cycles of 2 or more years. Consequently, if the seasonality were due to viral infections, a number of different viruses would have to be involved to be consistent with the remarkably stable seasonal and yearly incidence of T1DM.²⁷¹

The age pattern of onset of T1DM is in part compatible with an infectious etiology. T1DM is rare in the first 9 months of life. The incidence increases at about 5–6 years of age, peaks at approximately 12 years of age, and has a less well-defined peak at ages 20–35. No known infectious agent has an incidence pattern similar to this, but the low incidence rate of T1DM in the first months of life could be due to protection from infection by maternal antibodies, relative isolation during this period, or both. The increased incidence of T1DM at 5–6 years of age corresponds to the incidence pattern of many viral infections, which is high at this time, probably related to starting school.

Another epidemiologic observation supporting a pathogenetic role for environmental factors is the marked geographic variation in incidence of T1DM. Earlier studies had reported the age-adjusted incidence rates for T1DM with a 30-fold difference be-

FIGURE 20-7. Seasonal variation in onset of new cases of type 1 diabetes in children reported to the British Diabetic Association Register. (Reproduced with permission from Gamble.²⁷¹)

tween the population extremes; the highest incidence rate, 29.5/100,000 person-years, was found in Finland and the lowest, 1.6/100,000 person-years, in Hokkaido, Japan.²⁷² The EURODIAB collaborative group, established in 1988, prospectively analyzed geographically defined registers of new cases diagnosed under 15 years of age in 44 centers representing most European countries and covering a population of about 28 million children²⁷³; incidence rates ranged from 3.2 cases/100,000/y in the Former Yugoslav Republic of Macedonia to 40.2 cases/100,000/y in two regions of Finland. By pooling over all centers and sexes, the annual rates of increase in incidence were 6.3% for children aged 0–4 years, 3.1% for 5–9 years, and 2.4% for 10–14 years. The very rapid rate of increase in children aged under 5 years has been a matter of particular concern.²⁷³ The Diabetes Mondiale (DiaMond) Project Group recently reported the patterns in incidence of childhood T1DM worldwide²⁷⁴; the overall age-adjusted incidence of T1DM varied from 0.1/100,000/y in China and Venezuela to 36.8/100,000/y in Sardinia and 36.5/100,000/y in Finland. This represents a >350-fold variation in incidence among the 100 populations worldwide.²⁷⁴ This marked difference in incidence is much greater than for most other chronic diseases.²⁷⁵ Worldwide, a significant correlation was noted between T1DM incidence and average yearly temperature, but this must be interpreted with great caution given the plethora of other factors including diet, gene pool, and ethnicity that also vary geographically in a south to north gradient in the Northern Hemisphere. There are also exceptions to this apparent gradient, with the island of Sardinia being noteworthy. The incidence of T1DM in Sardinia is very similar to Finland.²⁷⁶ This picture is further complicated by the observation that within the relatively homogeneous Swedish population, T1DM incidence appears to be geographically determined, with high incidence areas only a short distance from areas with consistently lower incidence rates.²⁷⁶

Recent findings of time and space clustering of birth dates for later cases of diabetes together with the early observation of a very high prevalence of diabetes in cases with rubella embryopathy suggest that fetal virus exposure may be important.²⁷⁷ In early perinatal life the immune system is inducible, and exposures in this

period may initiate autoimmunity. Findings from Sweden and Finland suggest that enterovirus exposure during fetal life may initiate autoimmunity, leading to diabetes.²⁷⁷ In addition, food components such as nitrosamine components, cow's milk protein, and gliadin have been proposed to initiate the autoimmune β -cell destruction of T1DM.^{277,278} The diversity of determinants that are associated with T1DM risk points at a complex interaction between the genome and environment, and multivariate analyses have disclosed different risk profiles in different age groups.²⁷⁷ Most of these epidemiologic findings are supported by experimental studies in NOD mice, but their exact mechanisms of action are still unclear. Evidence has been accumulating indicating that perinatal exposures may be important for the initiation of β -cell destruction. Such risk factors may be the targets for primary prevention strategies of T1DM.²⁷⁷ As discussed earlier, evidence supports the concept that a neonatal wave of β -cell apoptosis precedes insulinitis in spontaneous, induced, and accelerated models of autoimmune diabetes, and the wave of apoptosis provides the antigen necessary for priming the β -cell-specific T cells.²⁰ However, since this neonatal wave of β -cell apoptosis is present in both diabetes-prone and diabetes-resistant animal models, it is believed that other factors (defective APC function, defective clearing of apoptotic debris) determine who goes on to develop autoimmune diabetes.²⁰

The precise mechanisms whereby environmental factors contribute to the pathogenesis of human T1DM are not known. Some of the possibilities include the following: (1) the agents may be directly toxic to the β cells and acutely cause sufficient loss of insulin secretory capacity to result in diabetes; (2) the agents, by an effect on the β cells, may trigger an autoimmune response directed against the β cells; (3) the agents, by providing specific peptides that share antigenic epitopes with host-cell protein ("molecular mimicry") may trigger an immune response against β cells; (4) the agents may cause insulin resistance, with resultant increased insulin needs that cannot be met because of prior β -cell damage; and (5) the agents may alter the β cells in a way that increases their susceptibility to damage by other mechanisms (Table 20-7).

TABLE 20-7. Possible Environmental Mechanisms in Type 1 Diabetes

1. Directly toxic to β cells
2. Trigger an autoimmune reaction directed against the β cells
3. Trigger an immune response by "molecular mimicry"
4. Induce increased insulin need that can not be met by damaged β cells
5. Alter β cells to increase susceptibility to damage

Potential environmental factors fall into three main groups: specific drugs or chemicals, nutritional constituents consumed in the diet, and viruses. Even a protective rather than destructive role has also been suggested for specific viral and bacterial antigens.²⁷⁹ It is also of interest to note that a pathogen-free environment increases diabetes in BB rats and NOD mice and that in NOD mice nonspecific immune stimulation is usually protective.^{279,280} As we live in a "cleaner environment," the decreasing chances of natural infection in the general population may contribute to the induction of autoimmunity because the developing immune system is not exposed to the stimulation that may be necessary to generate regulatory cells involved in the modulation and prevention of autoimmunity.²⁸¹

Drugs

Specific drugs or chemicals include alloxan, streptozotocin, pentamidine, and Vacor. Alloxan is directly cytotoxic to β cells, resulting in rapid and selective β -cell destruction, and is frequently used to induce T1DM in experimental animals. Alloxan is a uric acid derivative and is structurally very different from the other drug commonly used to induce diabetes, streptozotocin, which also causes direct β -cell lysis and is used therapeutically in humans to treat malignant insulinomas. In susceptible strains of mice, the β -cell damage induced by multiple subdiabetogenic doses of streptozotocin appears to elicit β -cell autoimmunity, which further contributes to β -cell loss.²⁸² Consequently, at a mechanistic level, this model provides evidence that a primary β -cell insult can result in secondary β -cell autoimmunity.

Pentamidine (4-4'-diamidino-diphenoxy-pentane) is a drug commonly used in the treatment of *Pneumocystis carinii* and is a recognized cause of drug-induced diabetes.²⁸³ Shortly after receiving the drug, hypoglycemia may be observed, due to release of insulin from damaged β cells, followed subsequently by overt diabetes due to β -cell destruction. Vacor is a rodenticide that, when ingested in large quantities by humans in suicide attempts, causes insulin-dependent diabetes. The major mechanism underlying the diabetes in these patients appears to be direct β -cell toxicity, but these patients also provide evidence that primary β -cell damage can result in secondary autoimmunity, as islet cell antibodies occasionally are found.²⁸⁴

Except in rare cases, it is unlikely that drugs or chemicals in the external environment are common and/or major etiologic factors in human T1DM. The observations cited are primarily important because they document that β cells are uniquely sensitive and can be selectively destroyed by certain chemicals and that primary β -cell damage can elicit an immune response directed against the β cells. The latter view is also supported by studies in transgenic mice expressing lymphocytic choriomeningitis virus (LCMV) in their β cells.²⁸⁵⁻²⁸⁷ Animals are tolerant to the transgene and remain nondiabetic until infected with the virus exogenously. They

then develop an immune response to LCMV, severe insulinitis, and T1DM.²⁸⁸

Dietary Factors

Among the environmental triggers, exposure to cow's milk in early neonatal life and development of T1DM has received considerable attention.²⁸⁹⁻²⁹¹ The hypothesis was developed more than a decade ago, and the issue is still not settled.^{265,292-295} Literature review shows that as many as 19 groups from different parts of the world have implicated exposure to cow's milk protein in early neonatal life in the development of T1DM, whereas 6 other groups have found no such relationship.^{265,292-294,296,297} We now review the evidence for and against this hypothesis.

Epidemiologic and experimental evidence has suggested that denial of dietary cow's milk protein early in life may protect genetically susceptible children and animals from T1DM.^{298,299} Elimination of intact cow's milk proteins from the diet significantly reduced the incidence of T1DM in the spontaneously diabetic BB rat, the elimination being most effective when it occurred during the preweaning period.³⁰⁰ Conversely, in newly discovered diabetics (both rats and children), compared with nondiabetic controls, increased levels of antibodies to cow's milk proteins have been reported. Bovine serum albumin (BSA) was proposed as a candidate milk-borne mimicry antigen responsible for the diabetogenic cow's milk effect.³⁰⁰ Elevated anti-BSA antibodies have been observed in patients and diabetic rodents.^{301,302} The anti-BSA antibodies cross-react with a β -cell membrane protein of Mr 69,000 (known as p69 or ICA 69) and precipitate p69 from islet cell lysates. BSA-specific T cells have been detected that recognize a 17-amino acid sequence of BSA, known as ABBOS peptide (pre-BSA position 152-169), previously identified as a possible mimicry epitope.²⁹¹⁻³⁰³ ABBOS-sensitized T cells were reported in 28/31 children with recent-onset T1DM but not in nondiabetic controls. Cross-reactive T cells that recognize both Tep69 (dominant NOD T-cell epitope in ICA69) and ABBOS (dominant NOD T-cell epitope in BSA) are routinely generated during human and NOD mouse prediabetes.³⁰⁴ These findings suggest that bovine milk proteins (mainly BSA) might be an important environmental factor providing specific peptides that share antigenic epitopes with host cell proteins.³⁰⁵ High titers of antibodies have also been detected against β -lactoglobulin (BLG), in addition to BSA.²⁹⁸ An enhanced cellular immune response to dietary BLG may reflect a disturbance in the regulation of immune response to oral antigens in T1DM.^{306,307} This kind of defect may play a fundamental role in the development of β -cell autoimmunity in T1DM.^{306,307}

The clinical evidence relating a short duration of breastfeeding or early cow's milk exposure to T1DM has recently been critically reviewed.^{295,308} Ecologic and time-series studies showed a relationship between T1DM and either cow's milk exposure or diminished breastfeeding. In the case-control studies, patients with T1DM were more likely to have been breastfed for <3 months (OR 1.43) and to have been exposed to cow's milk before 4 months (OR 1.63). High dietary intake of cow's milk protein in the 12 months before the onset of diabetes symptoms was also associated with an increased risk (OR 1.84).^{299,309}

Results from the Childhood Diabetes in Finland Study Group showed that initially nondiabetic siblings who were ICA-positive also had increased levels of antibodies to cow's milk proteins and suggested that the immune response to cow's milk proteins may be related to progression to clinical T1DM.^{310,311} High milk consump-

tion in childhood (≥ 3 glasses daily) was associated with more frequent emergence of T1DM-associated autoantibodies than low consumption (< 3 glasses daily; adjusted OR 3.97), and the estimated RR of childhood milk consumption for progression to T1DM was 5.37 (range: 1.6–18.4) when adjusted for matching and sociodemographic factors, age at introduction of supplementary milk feeding, and genetic susceptibility markers.³¹² Moreover, it was shown that children with T1DM have higher levels of cow's milk protein antibodies than their HLA-DQB1-matched sibling controls and that these high levels of antibodies are independent risk markers for T1DM.^{313,314} The accumulated evidence provided the basis for recent recommendations by the American Academy of Pediatrics to avoid cow's milk exposure in young infants at risk of T1DM.^{315–317}

A recent study examined the composition of milk as well as its consumption together with diabetes incidence in 0–14-year-old children from 10 countries.³¹⁸ Total protein consumption did not correlate with diabetes incidence ($r = 0.402$, level of significance 25%, NS), but the consumption of the β -casein A¹ variant did correlate ($r = 0.726$, level of significance 2%). Even more pronounced was the relationship between β -casein (A¹+B) consumption and diabetes ($r = 0.982$, level of significance 0.01%). The ecologic associations shown in this report suggest the necessity to consider not just the role of total milk consumption or its time of introduction into the weaning diet, in the etiology of T1DM, but also the role of individual milk protein variants.

A multicenter trial is being conducted in Finland to test whether avoidance of dietary cow's milk protein (CMP) for at least the first 6 months of life in genetically at-risk infants prevents the subsequent development of T1DM during the first 10 years of life.²⁹⁶ This Trial to Reduce IDDM in Genetically at Risk" (TRIGR) project is a randomized, prospective trial and involves newborn infants with first-degree relatives who have T1DM. Those genetically determined to be at high risk are randomized to receive a baby formula free of cow's milk (containing a nonantigenic protein hydrolysate) or a conventional cow's milk-based formula. The intervention period is for a 6-month period, with a follow-up of 10 years. This would be a "true" primary prevention strategy.

Generation of insulin-specific T cells in early childhood may provide a pathogenic link between cow's milk and diabetes. Studies among the infants recruited in the TRIGR second pilot study suggested that primary cellular immunization to insulin might occur in infancy by oral exposure to bovine insulin (BI) present in cow's milk. At the T-cell level, this response is first specific for BI but spreads to include reactivity to human insulin (HI) as well.^{319,320}

On the other hand, a few other studies including two recent prospective studies found no apparent association between the development of antibodies to islet antigens and feeding patterns in high-risk infants with a first-degree T1DM relative, and there are reports that p69 and BSA are not antigenically cross-reactive.^{321–326} It was suggested that studies reporting increased humoral and cellular immunity to cow's milk proteins in children with T1DM often lack appropriate controls and standardization and do not, in themselves, establish a causal connection to disease pathogenesis.³²⁶ Harrison and Honeyman²⁹⁵ have recently suggested that the cow's milk hypothesis could be productively reframed around mucosal immune function in T1DM. Breast milk contains growth factors, cytokines, and other immunomodulatory agents including cytokines that promote functional maturation of intestinal mucosal tissues. In the NOD mouse model, exposure of the mucosa to in-

sulin (present in breast milk) induces regulatory T cells and decreases diabetes incidence. The mucosa is a major immunoregulatory barrier, and cow's milk happens to be the first dietary protein it encounters. The basic question is whether impaired mucosal immune function predisposes to T1DM.²⁹⁵ Additional supporting information and further studies are needed to establish a clear role for diet in the pathogenesis of T1DM.

Viruses

Many investigators, employing many different techniques and methodologies, have evaluated whether viruses play an etiologic role in T1DM. Virus-induced diabetes in animal models, *in vitro* studies, epidemiologic investigations, case reports in humans, and research focusing primarily on molecular and cellular mechanisms have all been reported.

Viral infections can cause diabetes in a variety of animal species, frequently with important similarities to human T1DM. Some of these include encephalomyocarditis (EMC) virus, coxsackie B viruses, Mengovirus 2T, and reovirus types 1 and 3.³²⁷ Although EMC virus has not been implicated in human T1DM, elegant studies in mice provide mechanistic information that may be applicable to other viruses and to human T1DM. EMC virus can induce T1DM in genetically susceptible strains of mice, and two antigenically indistinguishable strains of EMC virus have been identified; EMC-D can induce diabetes in $>90\%$ of infected animals, whereas EMC-B does not cause diabetes.³²⁸ Genetically these two strains differ by 14 nucleotides, and one amino acid at the 776th position, alanine, is critical for diabetogenicity of the EMC-D variant.³²⁹ This amino acid is located in the attachment site of the virus, and alanine increases the efficiency of viral attachment to pancreatic β cells.³²⁹ Only certain strains of mice are susceptible to EMC-D virus-induced diabetes, and this genetic susceptibility also appears to involve viral attachment. Genetically susceptible mice express more viral receptors on their pancreatic β cells.³³⁰

Although it is clear that, in certain animal species, viruses can cause diabetes and that sometimes the diabetogenic process is in part immune-mediated, the situation in humans is far more controversial. As a foundation for postulating β -cell viral infection in human T1DM, Yoon, Prince, and coworkers have shown that several human viruses including coxsackie B3, coxsackie B4, reovirus type 3, and mumps can infect human β cells *in vitro* and destroy them.^{331,332} Furthermore, in children dying with overwhelming viral infections, histologic examination of their pancreata revealed cytopathology in 5 of 7 cases of coxsackie B infection, 20 of 45 cases of cytomegalovirus infection, and 2 of 45 cases of congenital rubella.³³³ Two case reports are also worthy of mention. In the first, a 10-year-old boy died of ketoacidosis, and coxsackie B4 was isolated from his pancreas. This virus produced diabetes when injected into mice.³³⁴ In the second case, diabetes developed a few days after a coxsackie B5 infection, and virus isolated from the feces produced hyperglycemia when injected into mice.

Among the many viruses potentially involved in the etiology of human T1DM, three have received the greatest attention, namely, mumps, coxsackie, and rubella. There has been considerable speculation about the role of wild mumps virus and mumps vaccine in the onset of childhood diabetes. Numerous investigators have noted temporal associations between T1DM and mumps infections, although the proposed time interval between the reported viral infection and T1DM has ranged from several years to weeks or months.²⁷¹ Additional support for the possible association of

T1DM with mumps comes from observations that mumps virus can infect human β cells *in vitro*,³³⁵ that altered cytokine and HLA class I and II antigen expression results from mumps-infected human insulinoma cells,³³⁶ and that ICAs are common in nondiabetic children following mumps infection³³⁷; other reports challenge mumps as an etiologic factor.³³⁸ Available data about mumps and T1DM are incomplete and difficult to interpret.³³⁹ Recent evidence from animal studies has raised the possibility that immunization by vaccines can influence the pathogenesis of T1DM mellitus.³⁴⁰ The possibility that widespread vaccination against mumps might offer protection against T1DM has also been investigated. A decline in mumps antibodies in T1DM patients and a plateau in the rising incidence of T1DM after introduction of mumps vaccine has been reported from Finland.³⁴¹ However, there is no evidence that mumps-measles-rubella (MMR) mass vaccination programs have changed the incidence of diabetes mellitus in any population.³⁴⁰ Lindberg and associates³⁴² found no evidence that MMR vaccination during adolescence may trigger autoimmunity.

Several studies have indicated that enterovirus infections, especially with coxsackie B, are frequent at the diagnosis of clinical T1DM or may play a role in the initiation of the β -cell damaging process.³⁴³⁻³⁴⁶ The first prospective studies were recently published; they suggested that enterovirus infections can also initiate the process several years before clinical T1DM.^{347,348} Lonnrot and colleagues^{345,349} analyzed the role of enterovirus infections in the initiation of autoimmunity in children who were tested positive for diabetes-associated autoantibodies in a prospective study starting at birth (the Finnish Diabetes Prediction and Prevention Study). Enterovirus infections were detected in 26% of sample intervals in the case subjects and in 18% of the sample intervals in the control children ($p = 0.03$). A temporal relationship between enterovirus infections and the induction of autoimmunity was found; enterovirus infections were detected in 57% of the case subjects during the 6-month period preceding the first appearance of autoantibodies compared with 31% of the matched control children in the same age group (OR 3.7). The frequency of adenovirus infections did not differ between the patient and control groups. Their data implied that enterovirus infections are associated with the development of β -cell autoimmunity and provide evidence for the role of enteroviruses in the initiation of β -cell destruction.

Three other observations support a potential role for coxsackie B in the etiology of T1DM. First, human β cells are susceptible to coxsackie B viral infection, and second, this infection results in decreased insulin production.³⁵⁰ Third, coxsackie B viral infection of diabetes-susceptible mice results in increased β -cell expression of GAD³⁵¹ and GAD antibodies.³⁵² Finally, a portion of the GAD molecule shares homology to coxsackie B4,¹⁰⁸ and this portion of the GAD molecule appears to contain an immune-dominant epitope stimulatory to T cells from human T1DM patients.³⁵³ However, only some strains of coxsackie B virus are diabetogenic,³⁵⁴ and exposure to the more common nondiabetic strains probably confers protection against infection with the diabetic strains, similar to the protection afforded against EMC-D virus-induced diabetes by prior EMC-B viral infection.³²⁸

Molecular mimicry is one mechanism by which infectious agents (or other exogenous substances) may trigger an immune response against autoantigens (Tables 20-8 and 20-9). Structural similarity (molecular mimicry) between viral epitopes and self-peptides can lead to the induction of autoaggressive CD4+ as well as CD8+ T-cell responses.³⁵⁵ It has been proposed that a self-peptide could replace a viral epitope for T-cell recognition and

5. Stimulation of regulatory T cells
6. Stimulation of effector T cells

therefore participate in pathophysiologic processes in which T cells are involved. The tolerance to autoantigens breaks down, and the pathogen-specific immune response that is generated cross-reacts with host structures to cause tissue damage and disease.³⁵⁶ In patients with T1DM, mimicry related to viral infection has been proposed on the basis of sequence homology between GAD-65, an enzyme concentrated in pancreatic β cells,³⁵⁷ and coxsackievirus P2-C, an enzyme involved in the replication of coxsackievirus B.¹⁰⁸ Although cross-reactivity between coxsackievirus P2-C and GAD-65 has been demonstrated in mice, and an immune response to the homologous peptides is generated by immunization of mice with full-length P2-C proteins,³⁵⁸ cross-reactivity between GAD and coxsackievirus P2-C has not been consistently found in studies of T cells or serum antibodies from patients with diabetes.^{100,359} Furthermore, a search of databases identified 17 viruses with some homology to various fragments of GAD-65,³⁶⁰ indicating that cross-reactivity between GAD-65 and coxsackieviruses is not unique.³⁵⁶

Poliovirus vaccine, the only currently available enterovirus vaccine, can theoretically modulate the protection against other enteroviruses by inducing cross-reactive T-cell immune responses.³⁴⁰ Enterovirus-specific cellular immunity was recently studied in Estonian and Finnish children, with the aim of evaluating the level of responsiveness in two neighboring countries that have different poliovirus immunization practices and striking differences in the incidence of T1DM.³⁴³ The results showed that Finnish children have weaker cellular immunity against enteroviruses at the age of 9 months compared with Estonian children at the same age. This was most probably due to the difference in polio vaccination schedules; in Estonia live poliovirus vaccine is used and given at earlier ages than the inactivated vaccines in Finland; the result is stronger T-cell immunity, which cross-reacts with other enterovirus serotypes. This might explain the lower incidence of T1DM in Estonia if live poliovirus vaccine provides effective protection against diabetogenic enterovirus strains in Estonian children. In another study, the cellular immune response to enterovirus antigens was abnormal in children who tested positive for T1DM-associated autoantibodies,³⁶¹ and these results showed that the increased responses to virus-infected cell lysates were associated with the early phases of β -cell autoimmunity.

TABLE 20-9. Examples of Molecular Mimicry Potentially Related to Type 1 Diabetes

Pancreatic Antigen	Foreign Antigen
Insulin (IAA)	p73 protein of mouse endogenous retrovirus
GAD	PC2 protein of coxsackie virus
ICA69	ABBOS peptide of bovine serum albumin
38K	Cytomegalovirus
52K	Rubella virus

Lymphocyte proliferation responses to enterovirus antigens were analyzed in 41 children with new-onset T1DM, 23 children with T1DM for 4–72 months, and healthy control children in subgroups matched for HLA-DQB1 risk alleles, sex, and age.³⁴⁴ Data from this study suggested that T-cell responses to coxsackievirus B4 proteins, particularly to the antigens containing the nonstructural proteins of the virus, are increased in children with T1DM after the onset of the disease. However, in children with new-onset diabetes, responses were normal or even decreased. This phenomenon was specific for enteroviruses and could be caused by trapping of enterovirus-specific T cells in the pancreas. The currently available information supports the assumption that the role of enterovirus infections may be more important than previously estimated. Enterovirus infections are associated with increased risk of T1DM, but whether this association reflects a causal relationship remains to be determined.

In contrast to mumps and coxsackievirus, there is general agreement that congenital rubella infection causes T1DM in later life. The incidence of diabetes in the congenital rubella syndrome has not been definitely determined and may vary between different populations, but it appears to average approximately 10–20%.³⁶² Most importantly, the diabetes induced by rubella is similar genetically and immunologically to the T1DM occurring spontaneously in the absence of rubella, namely, susceptibility appears to be genetically associated with HLA-B8 and -DR3, and relative protection is associated with HLA-DR2.³⁶³ The viral infection appears to trigger an immune response directed against the β cells because both islet cell antibodies and insulin autoantibodies are commonly found in these patients.³⁶⁴ These similarities suggest that the diabetes associated with congenital rubella is not etiologically distinct but that rubella virus triggers at least some of the same mechanisms that are operative in most spontaneous cases of T1DM.

Rubella virus has also been demonstrated to infect human β cells and to result in impaired insulin production,³⁶⁵ and there is antigen homology between a rubella virus capsid protein and an epitope in an unidentified 52-kd islet protein.³⁶⁶ The similarity between these findings and those previously summarized for coxsackievirus make it tempting to speculate that molecular mimicry may be applicable to both viruses. Ou and coworkers³⁶⁷ examined cross-reaction between virus antigens and β -cell protein determinants to understand further the potential role of this mechanism in T1DM. Cellular immune responses to a panel of human β -cell protein peptides (GAD-65, GAD-67, and a 38-kd protein) and to a panel of peptides of viral proteins (rubella virus E1, E2 and C, coxsackie B4 virus P2-C) were studied in 60 T1DM subjects. Amino acids (252–266) induced responses of patients with recent-onset diabetes in proliferation assays at the highest frequency (77%), whereas GAD-67 (212–226) stimulated cellular responses at the highest rate (61%) in patients with late-onset diabetes. Rubella virus E1 (RVE1; 157–176) was recognized by all groups of patients at the highest frequency and with the largest amplitude among the viral peptides tested. T-cell clones specific to GAD-65 (252–266), GAD-65 (274–286), or GAD-67 (212–226) were tested in cytotoxicity assays for their responses to rubella virus peptides. Each of these T-cell clones cross-reacted with two to four rubella virus peptides, including RVE1 (157–176) and rubella virus E2 (RVE2; 187–107), again supporting a potential role for molecular mimicry.

Recent data have reported an association of rotavirus infection and T1DM.^{368,369} Rotavirus, the most common cause of childhood gastroenteritis, contains peptide sequences highly similar to T-cell

epitopes in the islet autoantigens GAD and tyrosine phosphatase IA-2 (IA-2), suggesting that rotavirus could also trigger islet autoimmunity by molecular mimicry. Honeyman and colleagues^{368,3} sought an association between rotavirus infection and islet autoantibody markers in children at risk for diabetes who were followed from birth. There was a specific and highly significant association between rotavirus seroconversion and increases in three antibodies: 86% of antibodies to IA-2, 62% to insulin, and 50% to GAD first appeared or increased with increases in rotavirus IgG or IgA. It appears that rotavirus infection may trigger or exacerbate islet autoimmunity in genetically susceptible children. However, rotavirus infection is ubiquitous, occurring in all children, and hence the specific role in the small percentage that develop T1DM, usually many years later, is not clear.

With the exception of diabetes associated with congenital rubella infection, the large amount of research investigating a viral component to the etiology of human T1DM has raised as many questions as have been answered. Several different mechanisms have been suggested (Table 20-8), and these may not be mutually exclusive. Viral infections can directly damage β cells. Massive and sudden β -cell destruction may occasionally cause T1DM, whereas a smaller degree of injury may provide the initial insult that activates dormant autoimmune responses or the final insult to β cells previously damaged by a long autoimmune attack. It is also very likely that viral infections can act as a nonspecific, precipitating factor by causing insulin resistance and increased insulin needs. If prior β -cell damage and destruction make it impossible to meet the increased insulin demand, clinical diabetes would ensue.

Molecular mimicry, as discussed earlier, is considered the most attractive mechanism: viral infections might trigger subsequent immune-mediated β -cell destruction. The process of molecular mimicry and the use of transgenic models in which viral and host genes can be manipulated to analyze their effects in causing autoimmunity have been particular objects of research.³⁷⁰ For example, there is a transgenic murine model of virus-induced autoimmune disease, in which a known viral gene is selectively expressed as a self-antigen in β cells of the pancreas. In these mice, insulin-dependent diabetes develops after either a viral infection, the release of a cytokine such as IFN- γ , or the expression of the costimulatory molecule B7.1 in the islets of Langerhans. Recent studies using this model have contributed to the understanding of the pathogenesis of virus-induced autoimmune disease and have furthered the design and testing of novel immunotherapeutic approaches.^{370,371} Perhaps the most convincing evidence supporting this mechanism comes from transgenic mice expressing LCMV in their β cells.^{286,287} Animals are tolerant to the transgene and remain nondiabetic until infected with the virus exogenously. They then develop an immune response to LCMV, severe insulinitis, and T1DM.²⁸⁸

Viral infections may also protect against T1DM. Infection with a nondiabetogenic strain of a virus can elicit an immune response that protects against subsequent infection with a diabetogenic strain, as demonstrated for EMC virus.³²⁸ Viral infections can also directly affect the immune system and result in resistance to T1DM. In both the NOD mouse and BB rat, infection with a lymphotropic virus confers protection against the development of diabetes. In the BB rat, Kilham's rat virus appears to affect the immune system directly and to increase the population of immune cells mediating the T1DM.³⁷² von Herrath and colleagues³⁷³ have recently described an intriguing approach to the prevention of autoimmune disease, in which a DNA vaccine encoding a self-antigen

is used to abrogate autoimmune diabetes. The success of this strategy relies on the nature of the immune response induced by the DNA vaccine. Finally, environmental factors that alter β -cell activity may alter the β -cell susceptibility to injury and/or alter the β cells' repair mechanisms. It has been demonstrated that stimulated β -cells are more susceptible to cytokine-induced inhibition of insulin secretion and cytotoxicity,^{214,374} and recovery from a brief exposure to streptozotocin is improved by culturing islet cells in a high glucose-containing medium.³⁷⁵

SUMMARY

Dramatic advances have been made in recent years in our understanding of the pathogenesis of T1DM. Using this information plus genetic and immunologic measurements, nondiabetic individuals can now be identified who are at high risk of subsequent clinical T1DM. In turn, this ability to identify high-risk subjects and to predict subsequent clinical T1DM plus knowledge of pathogenic mechanisms has set the stage for large-scale intervention trials to test whether T1DM can be prevented (the Diabetes Prevention Trial-Type 1 [DPT-1]; the European Nicotinamide Diabetes Intervention Trial [ENDIT]; the Finnish Diabetes Type 1 Prediction and Prevention Project [DIPP]; and the Trial to Reduce IDDM in Genetically at Risk [TRIGR]). The long-term goal of researchers working in this field may soon be realized; the T1DM disease process may be susceptible to interruption, and some people may be prevented from developing clinical T1DM.
